Standard history, physical examination, laboratory studies including HLA typing and panel reactive antibody percent, infectious disease exposures, evaluation of cardiopulmonary status, and age- and sex-specific cancer screenings are performed as for other potential transplant recipients. In addition, confirmation of the diagnosis of type 1 diabetes mellitus is performed by measuring the serum C-peptide level; patients with type 1 diabetes mellitus should have undetectable levels of C-peptide, confirming a lack of insulin production. Complications seen with long-term diabetes may complicate the transplant procedure and postoperative management. Vascular disease in the coronary, lower extremity, and cerebral vessels is common and should be assessed. Severe gastroparesis may make oral administration of immunosuppressive medications difficult, requiring aggressive management with promotility agents. Blindness is not a contraindication to transplantation, but adequate social support to aid with medication compliance is required.

Patients with ESRD and type 1 diabetes are candidates for SPK transplantation. The added surgical risk of transplanting a pancreas is relatively low. Because of a shortage of suitable pancreas allografts, many type 1 diabetic patients are more likely to receive a renal allograft from either a living or deceased donor. These patients may be excellent candidates for PAK transplantation as they are already on immunosuppressive medications. Although this approach requires a second operation for pancreas transplantation and exposes the recipient to a second set of donor antigens, it is a growing option for many diabetic uremic patients. For nonuremic diabetic patients, the decision to proceed with PTA requires that the current complications (i.e., hypoglycemic unawareness, brittle diabetes, frequent hospitalizations) be of significant burden to offset the risks of surgery and lifelong immunosuppression.

PROCEDURE

Proper selection and preparation of donor organs require an experienced team. Ideal donors are between 10 and 50 years of age, are thin, have no surgical or traumatic damage to the pancreas, and do not have type 1 or type 2 diabetes mellitus. Intraoperative assessment of the potential pancreas allograft by the transplanting team is essential with attention paid to the size of the gland and vessels, fat content, and presence of fibrosis. Back-table preparation of the pancreas graft involves removal of the spleen and ligation of the splenic vessels, shortening of the bowel left with the graft, and

preparing the portal vein and superior mesenteric (SMA) and splenic arteries for implantation. A donor iliac artery Y graft may be attached to these SMA and splenic arteries to simplify arterial anastomosis to the donor.

Significant variation exists in the techniques of pancreatic transplantation. The goals of the operation are establishment of arterial inflow from the recipient iliac artery into the donor Y graft, portal venous outflow to either the systemic (iliac vein or IVC) or portal venous systems via the superior mesenteric vein, and drainage of the exocrine secretions of the pancreas into either the recipient bladder or bowel [see *Figure 4*]. Portal venous drainage of the pancreas allograft mimics the normal physiology of first-pass metabolism in the liver and may provide immunologic benefit.³³ Currently, the majority of pancreas grafts have exocrine drainage into the recipient jejunum. Bladder drainage requires that the duodenum and head of the pancreas be oriented in the recipient's pelvis. The advantages to bladder drainage of pancreas grafts include the ability to monitor urine amylase levels as a marker of rejection and decreased morbidity of anastomotic leaks. The disadvantages of bladder drainage include metabolic acidosis from pancreatic bicarbonate secretion, cystitis, and hematuria from constant mucosal exposure to pancreatic enzymes; reflux pancreatitis from urine entry into the pancreatic duct; and urethral injury. The advantages to enteric drainage include a more physiologic management of pancreatic secretions and more options for placement of the pancreas graft relative to vascular reconstructions. The main disadvantage to enteric drainage is the significant morbidity in rare cases of leakage from the enteric anastomosis.

COMPLICATIONS

Early postoperative thrombosis occurs in fewer than 5% of transplants but often requires removal of the graft. Portal vein thrombosis happens more frequently than arterial thrombosis and is the most common nonimmunologic cause of pancreatic graft failure. The etiology of thrombosis is not always clear, but many centers report use of antiplatelet agents and heparin-based anticoagulation. Venous thrombosis may be seen on Doppler ultrasonography. Early intervention may result in salvage of the graft, but graft loss is often the result.^{34,35}

Other early technical complications of pancreas transplantation include postoperative hemorrhage and, rarely, leakage from the duodenal anastomosis. Given the multiple vessels in the peripancreatic tissues and mesentery of the graft and the common use of anticoagulation following pancreas transplantation, bleeding complications are common. Hemodynamic instability or significant transfusion requirement may require exploratory laparotomy for hemostasis and to remove hematoma. Additionally, lower gastrointestinal bleeding may occur several days after pancreas transplantation, occasionally requiring blood transfusion support. Potential etiologies include mucosal sloughing from the transplanted duodenum or bleeding from the cut edges of the duodenal-jejunal anastomosis.

Elevated pancreatic enzymes are expected in the immediate posttransplantation period but should demonstrate a rapid decline. Persistent elevation or elevation of enzymes later in the patient's course should prompt further investigation for vascular thromboses or episodes of acute rejection. Imaging studies can confirm vascular patency, whereas tissue

Figure 4 Pancreatic transplantation. Iliac Y graft reconstruction of superior mesenteric and splenic arteries, systemic drainage of graft portal vein, and duodenojejunostomy.

diagnosis is required for suspicion of rejection. In SPK transplants, it is uncommon (1 to 2% of cases) to have pancreas rejection without kidney rejection and an elevated creatinine. Percutaneous kidney biopsy is often more easily performed than pancreas biopsy and can provide histologic evidence of rejection. In PAK transplantation or PTA, image-guided biopsy of the pancreas is often necessary to diagnose rejection. Bladder-drained pancreas grafts offer two advantages in the diagnosis of rejection: (1) rejection results in a decrease in urinary amylase excretion and (2) cystoscopic transduodenal biopsy of the pancreas allograft may be performed. Of note, hyperglycemia occurs only after destruction of substantial beta-cell mass and thus is a late marker of pancreas rejection.

OUTCOMES

All forms of pancreas transplantation (SPK, PAK, PTA) have shown improved outcome over the past 20 years despite the increasing use of high-risk donors and recipients.³⁶ Patient survival for all forms of pancreas transplantation is similar, although the best pancreas graft survival rates are seen with SPK transplantation⁸ [see Table 3].

Intestinal Transplantation

Approximately 1,700 small intestinal transplantations have been performed in the United States over the past 20 years with 2% of grafts donated by living donors.¹ Small intestinal transplantation is indicated in patients with intestinal failure

Table 3 Patient and Graft Survival Following Pancreas Transplantation^a

Survival (yr)	SPK	PAK	PTA
Patient			
1	95.2	97.8	98.2
5	85.4	83.4	87.2
10	67.4	61.1	68.6
Pancreas			
1	87.1	77.4	85.1
5	71.6	59.4	52.3
10	54.1	25.8	18.6

PAK = pancreas after kidney; PTA = pancreas transplantation alone;
SPK = simultaneous pancreas-kidney.

attributed to extensive small bowel resection, severe malabsorption, or motility disorders. A detailed description of the selection processes, surgical procedures, and complications is beyond the scope of this text. An excellent review is available.³⁷

Immunology and Immunosuppression

PRINCIPLES OF IMMUNOLOGY

Immune-mediated destruction of an allograft, or rejection, requires a multistep process in the recipient. First, antigens from the donor are presented in the context of recipient major histocompatibility complex (MHC, also known as HLA) by recipient antigen-presenting cells. Recipient T cells bind to the MHC-antigen complex via the T cell receptor (TCR). Binding is not sufficient to activate the immune system, however, as costimulatory signals are also required to allow internalization of the TCR and activation of the cell to produce interleukin-2 (IL-2). IL-2 acts to stimulate proliferation of T cells, thus augmenting the immune response. Other cytokines and chemokines are also elaborated that serve to activate various other aspects of the immune system, including B cells, complement, neutrophils, and natural killer cells. Immunosuppressive agents block various steps in these pathways.

Rejection may be classified by the timeframe of occurrence and the types of reactions that occur. Hyperacute rejection results immediately on reperfusion of the allograft and is attributed to the presence of preformed antibodies against HLA class I or ABO blood antigens circulating in the recipient. These antibodies attach to the donor organ vascular epithelium, fix complement, attract neutrophils, and destroy the endothelium within minutes to hours, resulting in near-immediate graft loss. The crossmatch performed prior to transplantation mixes donor lymphocytes with recipient serum to detect these preformed antibodies. Accelerated rejection may occur if the recipient has had prior sensitization to donor antigens but does not have circulating antibody. Memory responses allow for a rapid proliferation of T cells or antibodies against the antigens of the graft.

In the absence of immunosuppression, acute rejection occurs toward the end of the first week following transplantation. Nonspecific inflammatory processes including infiltration

with mononuclear cells, edema, and decreased blood flow in combination with destruction of parenchymal and endothelial cells by lymphocytes leads to blood vessel destruction and loss of function. Acute rejection may also occur at any time that insufficient immunosuppression exists in the recipient. If detected early, acute rejection may be reversed by increased immunosuppression, but long-term outcomes of renal grafts having episodes of acute rejection are diminished compared to those grafts without this complication. Acute cell-mediated rejection in the kidney is characterized by interstitial mononuclear cells and disruption of tubular basement membranes, or tubulitis. In liver allografts, histologic evidence of acute rejection includes portal infiltrates consisting of mixed inflammatory cells, lymphocyte-mediated bile duct injury, and endothelialitis. In acute antibody-mediated (humoral) rejection, endothelial swelling and arteritis, glomerulitis with neutrophils, and plasma cell infiltration can occur. Immunohistochemical staining for complement components (C4d) also suggests humoral rejection. Measurement of serum donor-specific antigens levels may help confirm humoral rejection. Of note, cellular and humoral rejection may coexist.

Chronic rejection refers to the gradual loss of function of a transplanted organ. Its pathogenesis is not fully understood but may be related to immunologic and other factors. Across organs, intimal thickening, parenchymal atrophy, and interstitial fibrosis are common findings. Following renal transplantation, chronic rejection is also known as chronic allograft nephropathy and is characterized by interstitial fibrosis and tubular atrophy. Chronic rejection after liver transplantation is reflected in scarring of the bile ducts (vanishing bile duct syndrome). Current immunosuppressive medications do not prevent or reverse chronic rejection, although episodes of acute rejection may set the stage for chronic rejection despite apparent resolution.

IMMUNOSUPPRESSIVE AGENTS

Immunosuppressive agents may be divided into induction agents, usually given only around the time of transplantation or to treat rejection, and maintenance agents, given continuously after transplantation. Induction agents are typically used once or for a few doses in combination with initiation of maintenance agents at the time of transplantation. Antilymphocyte and antithymocyte globulins are polyclonal antibodies directed at multiple antigens of lymphocytes. OKT3 is a monoclonal antibody directed against the TCR (CD3). The side effects of these agents include acute cytokine release syndromes, allergic reactions, and development of neutralizing antibodies to OKT3. Because of their potent effects, prolonged use may also increase the risk of opportunistic infection or lymphoma. CD25 forms part of the interleukin-2 receptor (IL-2R) on activated T cells. Two monoclonal antibodies against CD25, basiliximab (Simulect) and daclizumab (Zenapex), bind the IL-2R and prevent activation of the cell. Alemtuzumab (Campath), another monoclonal antibody, targets CD52 and results in a profound depletion of lymphocytes for several months.

Maintenance agents are used in various combinations to provide ongoing immunosuppression. The number of agents and the doses or target blood levels may be decreased as the rejection-free time from transplantation accumulates. Corticosteroids have many effects on the immune response,

including general antiinflammatory properties and inhibition of cytokine production and secretion by altering gene transcription. Prolonged use of corticosteroids results in many side effects, including weight gain, diabetes, hypertension, peptic ulcers, muscle wasting, osteopenia, cataract formation, personality changes, and cushingoid changes. CNIs, cyclosporine (Sandimmune, Neoral) and tacrolimus (Prograf), block the TCR from signaling through immunophilin to stimulate IL-2 production. The side effects of the CNIs include nephrotoxicity, hypertension, hyperkalemia, and neurotoxicities. Cyclosporine is also known to cause hirsutism and gingival hyperplasia, whereas tacrolimus may cause alopecia and has been associated with an increased incidence of posttransplantation diabetes. For both agents, blood levels are monitored carefully to maintain adequate immunosuppression and minimize side effects. The metabolism of many medications affects or is affected by these agents; thus, addition or cessation of medications should be done in conjunction with the transplant center. Rapamycin or sirolimus (Rapamune) blocks the IL-2R signal to the T cell nucleus and stops cell-cycle progression. Rapamycin may contribute to hypertriglyceridemia, limits wound healing, and has been linked to HAT. Antiproliferative agents prevent clonal expansion of activated lymphocytes as well as other rapidly dividing cells, including the gastrointestinal tract and hematopoietic cell lines. Azathioprine (Imuran) was the first agent in clinical use, whereas mycophenolate mofetil (CellCept, Myfortic) is now commonly used. The side effects include gastrointestinal toxicity and leukopenia.

Pre- and posttransplantation protocols exist for transplantation between ABO-incompatible donor and recipient pairs, for patients with a positive cytotoxic crossmatch, and for patients with high PRA attributed to prior transplantation, transfusion, or pregnancy. A detailed discussion of these topics is beyond the scope of this review.

General Surgery in Patients with End-Stage Organ Disease

END-STAGE RENAL DISEASE

General Principles

As kidney transplant waiting list times may exceed 5 years in some regions, it is likely that most practitioners will encounter patients with ESRD who have general surgery problems. Coordination of the patient's care with a nephrology team and careful management of the patient's volume status and electrolytes are crucial to a successful outcome. The effect that comorbid conditions, including coronary artery disease, congestive heart failure, and peripheral vascular disease, may have on the safe conduct of the operation or perioperative management cannot be minimized. Use of desmopressin (ddAVP) aids in correcting uremic coagulopathy by increasing factor VIII and von Willebrand factor, whereas platelet transfusion may be needed in patients requiring emergent surgery who have been on aspirin or other antiplatelet agents. Additionally, patients with ESRD have poor wound healing attributed to a combination of nutritional factors, depressed immune function, and poor circulation. Chronic renal failure and dialysis lead to a hypercatabolic state attributed to loss of amino acids and cytokine

activation.³⁸ ESRD has an immunosuppressive effect because of decreased neutrophil function, impaired phagocytosis, reduced natural killer cell activity, and decreased lymphocyte function.³⁹ Strict glycemic control in the perioperative period has also been shown to decrease infectious complications, although differences in mortality were not seen in a recent meta-analysis of studies comparing tight glucose control to usual care.⁴⁰ Careful surgical technique combined with appropriate antibiotic management, nutritional support, and maximal medical management of comorbidities is required for good outcomes in this population.

General and Peripheral Vascular Surgical Procedures

Patients with ESRD exhibit many of the same general surgical diagnoses as patients with normal renal function. In a comparison to patients without ESRD, laparoscopic cholecystectomy was performed in patients with ESRD with no difference in blood loss, conversion rate, morbidity, mortality, or hospital length of stay.⁴¹ Similarly, patients with ESRD may undergo liver resection for HCC with no difference in overall and disease-free survival despite more associated disease, more postoperative complications, and longer hospital stays than patients without ESRD.^{42,43} *Clostridium difficile*-associated colitis, diverticulitis, and mesenteric ischemia are all common diagnoses in patients with ESRD and often result in increased morbidity and mortality in this population.⁴⁴⁻⁴⁶ Patients with polycystic kidney disease appear to be at increased risk of complicated diverticulitis than patients with other etiologies of renal failure.⁴⁶ Segmental necrosis of the ascending colon has been frequently reported in dialysis patients and is likely caused by low-flow states and changes in blood viscosity.⁴⁷⁻⁴⁹ In patients managed with PD, a high degree of suspicion should be maintained to differentiate acute surgical diagnoses from peritonitis caused by infected peritoneal dialysate fluid. Although peritonitis as a result of contamination of the dialysate or system is most common, other causes should be considered. An 8-year review of a single center found six cases of peritonitis in PD patients caused by a perforated appendix or diverticulitis with a mortality of 16%.⁵⁰ The average time to diagnosis in this group was 10 days, with CT of the abdomen being nondiagnostic in all cases.⁵⁰ Clinical and radiologic findings may be nonspecific, but the presence of polymicrobial infection should prompt further investigation.

Patients with ESRD are at increased risk for peripheral vascular disease. The stage of chronic kidney disease (CKD) has been found to predict survival curves and risk for major amputation in patients undergoing lower extremity bypass surgery.⁵¹ In comparison to patients with CKD and patients with normal renal function, patients with ESRD have similar perioperative mortality and graft patency rates but a higher rate of amputation despite a patent graft.⁵² Patients with ESRD appear to have an increased risk of more distal vascular lesions (popliteal-tibial) compared to more proximal (aortoiliac) lesions, which may influence the type of reconstruction required.⁵³

Obese patients suffer increased complications following surgery, including renal transplantation. To address perioperative morbidity as well as long-term health concerns, several centers have recently reported performing bariatric surgery in patients with ESRD prior to renal transplantation.⁵⁴⁻⁵⁶ One group reported that 93% of patients reached institutional

body mass index limits for transplantation, and obesity-associated comorbidities resolved or improved in all patients.⁵⁵ Similarly, several series reported improvement in renal function following bariatric surgery, in some cases obviating the need for renal transplantation.^{57,58}

Vascular Access Procedures

Vascular access options for long-term hemodialysis (HD) include arteriovenous fistula (AVF; direct connection of artery and vein), arteriovenous grafts (AVGs; artery and vein connected with prosthetic material), and catheter-based dialysis. Use of AVFs has been shown to have lower rates of complications (thrombosis or infection) and results in fewer hospitalizations, less morbidity, and less cost than use of AVGs or catheter-based dialysis.^{59,60} The National Vascular Access Improvement Initiative, sponsored by the Centers for Medicare and Medicaid, sought to reach the goal of AVF creation in at least 50% of all new patients starting HD and 40% of prevalent patients on HD.⁶¹ This “Fistula First” campaign promotes early identification and referral of patients with CKD for consideration of AVF creation in time for maturation of the fistula by the time it is needed to start HD. Recent reports suggest that AVF use increased in the United States from 24 to 47% from 1996 to 2007, whereas AVG use decreased from 58% to 50% over the same time period.⁶²

Assessment for placement of arteriovenous access starts with an emphasis on the likely time until the start of dialysis and prior attempts at access creation or central venous catheter placement. Ideally, access creation occurs several months prior to the need for dialysis to allow for maturation of the access. Severe heart failure may preclude fistula creation attributed to increased cardiac output required to support the fistula. On clinical examination, the status of distal pulses in the upper and lower extremities is assessed. Similarly, the superficial veins (cephalic, basilic) of the arm are assessed for patency or scarring from prior phlebotomy or previous attempts at access creation. If no veins are apparent or their patency is questionable, imaging studies such as ultrasonography or venography can be performed. Venography can also provide information about the patency of the central venous system in patients who have had prior central venous catheters. Once a site has been chosen, phlebotomy and peripheral intravenous line insertion should be performed in the contralateral arm. In choosing sites for access creation, the nondominant upper extremity is preferred, with the most distal site used first. A vein diameter of more than 2.5 mm is preferred, but use of smaller veins may be attempted if necessary.

Sites for upper extremity AVF creation in the distal arm include the radiocephalic (Brescia-Cimino), snuff-box, and ulnar-basilic fistulas [see Figure 5]. More proximally, a brachiocephalic fistula may be created just above or below the elbow crease. A brachio-basilic fistula may be created but will likely require transposition and elevation of the basilic vein either during the initial procedure or as a second, staged procedure once the vein has matured. Attempts to cannulate the basilic vein in its native position may be difficult because of its distance from the skin and may risk injury to the adjacent nerves and artery. Fistula creation can usually be performed under local or regional anesthetic. Most commonly, the vein is anastomosed in an end-to-side configuration to the artery, although side-to-side fistulas may also be used. At the end of

the case, a palpable thrill or audible bruit on the venous side of the fistula confirms patency. Postoperatively, patients are instructed to palpate the fistula daily to confirm the presence of a thrill. Exercises such as squeezing a rubber ball may help maturation of the fistula by increasing resistance to flow in the hand, thus increasing flow through the fistula. Maturation of the fistula implies that the venous limb has expanded to more than 6 mm and typically takes 4 to 6 weeks to occur. Lack of maturation may require ligation of branches of the vein or fistulogram to diagnose and potentially treat inflow (arterial) or outflow (venous) stenoses. AVGs can be placed when options for AVFs have been exhausted. The most commonly placed AVGs in the arm are straight grafts from the radial artery to basilic vein or loop grafts from the brachial artery to the basilic vein. The axillary artery can also be used with outflow via upper arm, neck, or chest veins. AVGs may be used once the graft material has been incorporated into adjacent tissues, thus preventing hematoma formation around the graft during cannulation. Two to 3 weeks is often required for incorporation and resolution of edema from placement.

Access creation in the lower extremity is usually reserved for patients who have no upper extremity options for access given a higher rate of wound infection and the need to preserve the saphenous vein as a conduit for future coronary artery bypass or lower extremity arterial reconstruction. Lower extremity fistulas may be constructed using transposed saphenous vein to connect the common femoral artery and vein. The saphenous vein may also be used as a loop (to the common femoral artery) or straight (to the distal superficial artery above the knee). Either leg vein may also be translocated to the upper extremity to create a loop or straight graft. AVGs may be created in the thigh but have higher risks of infection. An excellent review of AVF options is available.⁶³

Complications of AVFs and AVGs include failure of a fistula to mature, stenosis or thrombosis of the access, infection, ischemia or steal distal to the access creation, and pseudoaneurysm formation. Failure to mature may be due to use of small vessels, central stenosis, or competing flow through collateral vein branches. Stenosis may also occur at the anastomosis or at sites of turbulence or needle-stick injury. Poor flows through the access during dialysis sessions, persistent edema, prolonged bleeding, and a change in the nature of the thrill or bruit suggest stenoses that may be diagnosed and often treated by percutaneous interventions. Thrombosis may occur as a result of technical problems, hypercoagulable states, or persistent hypotension. A recent review suggested that use of antiplatelet agents including aspirin, clopidogrel, and dipyridamole decreased the risks of thrombosis in AVFs and AVGs, whereas use of warfarin resulted in unacceptably high rates of hemorrhagic events.⁶⁴ AVFs and AVGs may be at increased risk of thrombosis during unrelated surgical procedures. Care should be taken to protect fistulas and grafts from inadvertent pressure either on the access itself or central to it.

PD Catheter Placement

PD is an alternative to HD for many patients. Suitable candidates have had no or few prior abdominal operations with minimal adhesions and do not have ascites, malignancy, or fibrosis. Additionally, the patient or family should be motivated and able to perform PD in the home. Patients may opt

Figure 5 Upper extremity arteriovenous fistula (AVF) options include the (a) radiocephalic, (b) brachiocephalic, and (c) brachiocephalic fistulas.

for continuous ambulatory PD with four to five manual exchanges of fluid daily or continuous cycling PD, in which the patient is attached to a machine for automatic exchanges while sleeping. Catheter placement may be performed open or laparoscopically. The open technique uses an incision over the rectus sheath inferior to the level of the umbilicus. The rectus fibers are separated to expose the peritoneum to allow the creation of a small peritoneal incision. The catheter is inserted over a trocar through this incision and directed into the pelvis. One cuff is placed at the level of the fascia and may be secured in the fascial closure to avoid migration. The external end is tunneled in the subcutaneous tissues to an exit site remote from the fascial entry site. The skin exit site should be chosen to avoid interfering with clothing but in a position that is easy for the patient or caregivers to access. Use of laparoscopy for placement of PD catheters allows potential lysis of adhesions and direct placement of the catheter in the pelvis. Additionally, the catheter can be secured in the pelvis using a stitch to the anterior abdominal wall to avoid migration. Ideally, the catheter should not be used for 2 to 3 weeks to allow for healing and reduce the risk of leakage, but low-volume exchanges may be started sooner in urgent cases.

Complications of PD catheter placement include technical problems such as bowel injury, leakage from the fascial closure, malposition of the catheter, and obstruction of the catheter by omentum or adhesions. Some surgeons prefer to perform omentectomy during the initial placement of a PD catheter, whereas others prefer to wait and perform omentectomy only if there are problems with dialysate flow.

Laparoscopic revision may be attempted to reposition the catheter in the pelvis, lyse adhesions, or remove the omentum. Peritonitis and catheter tract and exit-site infections may also occur. Treatment of peritonitis using systemic and intraperitoneal antibiotics may be successful in some cases, whereas treatment of tract infections usually requires removal of the catheter. Over time, efficiency of solute exchange may decrease to the point that PD no longer provides adequate dialysis therapy, thus requiring conversion to HD.

END-STAGE LIVER DISEASE

General Principles

Whether emergent or elective, performing an operation on a patient with ESLD should be approached cautiously. The first step in appropriate management of the cirrhotic patient with a general surgery problem is determining the degree of underlying liver disease. Assessment of the severity of liver disease may be made using either the Child-Turcotte-Pugh (CTP) score or MELD score. The CTP score is calculated using the patient's serum albumin, serum bilirubin, prothrombin time, and presence or degree of ascites and encephalopathy.⁶⁵ Based on total score, patients are classified as Child's A, B, or C with increasing morbidity and mortality with increasing score. Another scoring system, the MELD score, was developed to predict 3-month mortality following transjugular intrahepatic portosystemic shunt (TIPS) creation in cirrhotic patients. The MELD score is based on the patient's serum bilirubin, serum creatinine, and INR for

prothrombin time. The MELD score is now used to determine the listing priority for liver transplantation and to provide a general gauge of the severity of liver disease. A recent comparison of the CTP and MELD systems demonstrated that a MELD score of 14 or greater was a better predictor of death, progression to liver transplantation, or prolonged hospital stay than a CTP class of C.⁶⁶ Following major digestive, orthopedic, or cardiovascular surgery, patients with MELD scores of less than 8 had a 30-day mortality of 6%, whereas patients with scores above 20 had a 50% mortality.⁶⁷ An online tool has been developed to determine the postoperative mortality following surgical procedures based on MELD score <<http://www.mayoclinic.org/meld/mayomodel9.html>>.

Once the underlying severity of liver disease has been established, the decision to operate and the timing of the operation depend on a number of factors, including the following:

1. Acuity of the problem (i.e., ruptured umbilical hernia versus asymptomatic hernia)
2. Options for nonoperative management (i.e., percutaneous cholecystostomy)
3. Availability of liver transplantation in case of hepatic decompensation
4. Likelihood of transplantation (i.e., defer repair of umbilical hernia if the MELD score is high)
5. Ability to use TIPS placement to manage ascites and portal hypertension⁶⁸
6. Ability to transfer the patient to the care of a transplant surgeon
7. Availability of consulting services (i.e., hepatology, radiology, anesthesia)
8. Ability to optimize the patient's medical status prior to operation
9. Skill and experience of the team to perform a specific intervention

If the decision is made to proceed with the operation, several general principles may aid in achieving a good outcome. Patients with advanced cirrhosis typically exhibit whole-body sodium overload despite serum hyponatremia. Administration of excessive sodium in the form of 0.9% normal saline will exacerbate formation of ascites, thus worsening volume overload and edema formation, putting stress on surgical incisions, and potentially compromising respiratory function. Minimization of sodium administration through the use of 5% dextrose in water solutions and albumin and judicious use of loop diuretics and aldosterone antagonists will aid in controlling ascites. Preservation of adequate intravascular volume and renal perfusion will help avoid precipitating pre-renal azotemia or hepatorenal syndrome.

Patients with cirrhosis and ESLD often suffer protein-calorie malnutrition and may have specific vitamin and micronutrient deficiencies.⁶⁹ Early enteral nutrition should be considered in all cirrhotic patients undergoing general surgical procedures. In patients with compensated cirrhosis, feeding goals should be 25 to 35 kcal/kg/day of nonprotein calories and 1 to 1.2 g/kg/day of protein; decreased amounts of protein are provided to patients with encephalopathy.⁶⁹ Use of branched-chain amino acid supplementation in patients with cirrhosis has variably affected outcome, but studies suggest an improvement in encephalopathy as well as mortality and quality of life.^{70,71} Preoperative use of immune-

enhancing diets containing components such as arginine, omega-3 fatty acids, and nucleotides has been shown to improve recovery after transplantation and decrease infectious complications.⁷² Use of such formulas may be beneficial in cirrhotic patients undergoing general surgical procedures. As patients with cirrhosis are often deficient in vitamins A and D and zinc, supplementation of these compounds should also be considered in the perioperative period. Finally, administration of vitamin K may aid in reversal of hemostatic deficiencies in those patients suspected of having poor preoperative nutrition, cholestasis, or infection. Use of parenteral nutrition should be avoided if possible given the risk of worsening liver function by promoting cholestasis.

Use of peritoneal drains after intra-abdominal procedures in patients with cirrhosis is controversial. Some surgeons advocate their short-term use in patients with tense ascites who have undergone surgery to provide a controlled means of draining ascites. This practice may allow peritonealization and initial sealing of surgical wounds, thus avoiding incisional ascites leaks, which can lead to postoperative bacterial peritonitis, wound dehiscence, or hernia formation. The presence of such drains, however, provides an entry site for bacteria, which may lead to peritonitis. Additionally, as the presence of drains will allow a low-pressure egress of ascites fluid, patients may lose a substantial amount of volume and protein if drain output is not carefully monitored and replaced. Postoperative ascites can often be managed with careful fluid and sodium balance, use of diuretic agents, and intermittent paracentesis in the case of tense ascites that is not controlled by medical therapy. TIPS placement may also be considered in carefully selected patients. Some authors advocate use of temporary PD catheters to allow at-home controlled drainage of ascites; however, because of concerns over infection and volume and protein loss, the use of this technique is not recommended.⁷³ A randomized, controlled trial of 104 patients with chronic liver disease who had elective hepatic resection showed that patients with drains had higher operative morbidity (mainly wound complications) and postoperative length of stay than the nondrained cohort.⁷⁴ In general, drains should not be left to manage ascites but may be considered for use in specific cases (i.e., concern for bile leakage after difficult cholecystectomy, after biliary reconstruction, or to drain an abscess cavity).

TIPS creation may be used in patients with intractable ascites or severe portal hypertension prior to elective surgery.⁶⁸ Contraindications to TIPS include encephalopathy, right-heart failure, and elevated bilirubin.

Abdominal Hernias

The incidence of symptomatic umbilical hernia is increased in patients with ESLD and ascites attributed to increased intra-abdominal pressure. The indications and timing of repair of umbilical hernias depend on whether the hernia presents as a surgical emergency and whether the patient is a candidate for liver transplantation. Hernias with thinned skin or eschars and ruptured or incarcerated umbilical hernias are repaired emergently. Repair of asymptomatic hernias in patients who are candidates for liver transplantation may be deferred until the time of transplantation. In patients who are not candidates for transplantation, multiple studies support elective repair of umbilical hernias.⁷⁵⁻⁷⁷ Failure of conservative management occurred in 77% of patients followed in one

series, resulting in hospital admission for incarceration, emergent repair in 46%, and death in 15% of patients.⁷⁵ Two other groups found that elective surgical morbidity in cirrhotic patients with umbilical hernia was the same as in noncirrhotic patients, whereas morbidity following emergent surgery was significantly increased.^{76,77} Based on the risks associated with observation of umbilical hernias in patients with cirrhosis and the increased risks of emergent surgery, elective repair in medically optimized patients appears to be the safest course.

In approaching umbilical herniorrhaphy in patients with cirrhosis, several technical points deserve consideration. If at all possible, maintenance of the integrity of the hernia sac should be attempted to decrease the risk of ascites leakage in the postoperative period. Small hernias may be closed without mesh, acknowledging that the risk of recurrence may be increased. Our preference is to close the subcutaneous tissues in multiple layers while the skin is closed using a running, locking nylon suture. We place a layer of skin adhesive (Dermabond or Indermil) over the suture line to provide another layer of protection from leakage. Sutures are removed 3 to 4 weeks postoperatively. Postoperative ascites is controlled as outlined above.

The management of inguinal hernias in patients with cirrhosis is not significantly different from that in noncirrhotic patients. One series reported the results of 13 inguinal or femoral hernia repairs in 11 patients.⁷⁸ There were no major complications and four minor complications, including two wound complications, and one case each of prerenal azotemia and encephalopathy.⁷⁸ Another group reported significant improvement in quality of life after repair of inguinal hernias, with the greatest benefit seen in patients with Child's class C cirrhosis and/or refractory ascites.⁷⁹ Despite these good results, any operation performed on patients with advanced liver disease carries increased risk of ascites leakage, bleeding, or decompensation.

Cholelithiasis

Multiple series have reported good outcomes with laparoscopic cholecystectomy for symptomatic cholelithiasis in patients with Child's class A and B cirrhosis.^{80–84} As seen in patients without cirrhosis, laparoscopic cholecystectomy results in less morbidity, shorter operative time, and reduced hospital length of stay when compared with open cholecystectomy.^{80–83} Series that included patients with Child's class C cirrhosis reported much higher morbidity and mortality with deaths as a result of liver failure and sepsis after laparoscopic cholecystectomy.⁸⁴ Even in open series, mortality for patients with Child's class C cirrhosis approached 25%.⁸⁵ Operative intervention appears reasonable for Child's class A and B patients, whereas those with Child's class C cirrhosis should be managed nonoperatively if possible (see below).

Intra- and postoperative hemorrhage or decompensation of previously stable liver disease are two major risks of laparoscopic cholecystectomy in patients with cirrhosis. In addition to careful surgical technique, several specific points deserve consideration in making the procedure safer. First, many patients with cirrhosis and portal hypertension have a recanalized umbilical vein. Therefore, initial periumbilical port placement should be done using an open technique to avoid lacerating this vein. Bleeding from the gallbladder fossa is a

common problem that can be managed with the laparoscopic argon beam coagulator. In cases where it is difficult to remove the back wall of the gallbladder from the gallbladder fossa, a patch of the back wall may be left attached and cauterized. Communication with anesthesia staff before and during the case will ensure appropriate fluid management and avoidance of hypotension, which may lead to renal or hepatic failure in the postoperative period.

For patients with more advanced liver disease (Child's class C or MELD score greater than 15 to 20), all efforts should be focused on avoiding operative intervention. Maximal medical management with bowel rest, intravenous fluids, and antibiotics may allow resolution of acute cholecystitis. In cases with persistent symptoms despite intensive management, placement of a transhepatic percutaneous cholecystostomy tube may be considered and has been used with some success.⁸⁶ The risks of this approach include hemorrhage from the liver during tube placement, ascites leakage around tube skin exit sites, and spread of infection into ascites. An alternative approach using ERCP-placed stents draining from the gallbladder into the duodenum has also been described.⁸⁷ In one series, 57% of patients had Child's class C cirrhosis and diagnoses of recurrent biliary colic, acute calculous and acalculous cholecystitis, and gallstone pancreatitis.⁸⁷ All patients were successfully treated with stents without major complications.⁸⁷

Disorders of the Intestine

Patients with cirrhosis may present with conditions requiring either emergent or elective surgery, including appendicitis, cancer, diverticulitis, and ischemic colitis. In the setting of imminent transplantation, indications for elective intervention may be deferred until after the transplantation has occurred. If the patient is not a candidate for transplantation or the indication requires urgent or emergent surgery, optimization of the patient and careful technique and perioperative management are the only options. A large series of patients with cirrhosis undergoing elective and emergent colorectal procedures demonstrated a high level of morbidity (77%) and mortality (26%).⁸⁸ Risk factors for poor outcome included Child's class B or C or preoperative presence of ascites, whereas a preoperative finding of peritonitis, occurrence of postoperative complications or infections, and the need for total colectomy all predicted mortality.⁸⁸ Appendicitis may occur in patients with cirrhosis. A comparison of open versus laparoscopic appendectomy in patients with cirrhosis demonstrated decreased pain, length of stay, wound infection, and bleeding complications in the laparoscopic group without a difference in overall hospital cost.⁸⁹

Patients with concomitant PSC and ulcerative colitis present a special dilemma to treating surgeons. Assessment of the relative degree of disease in each organ aids in determination of the order of colectomy and liver transplantation, if indicated. Either extreme of the spectrum presents a relatively straightforward course: acute, toxic megacolon unresponsive to medical management in the setting of mild liver disease necessitates urgent colectomy, whereas mild dysplasia in the setting of advanced cirrhosis warrants liver transplantation followed by colectomy. Use of a living donor for liver transplantation could also be considered in this setting. Successful combined liver

transplantation and total abdominal colectomy followed by delayed ileal pouch-anal anastomosis (IPAA) has also been reported.⁹⁰ Laparoscopic proctocolectomy with IPAA in patients with mild liver disease from PSC has been shown to be feasible, with decreased hospital stay and no difference in complications when compared to the open procedure.⁹¹ Numerous reports support an increased incidence of colorectal cancer in patients who have undergone liver transplantation for PSC.^{90,92} Vigilant colonoscopic surveillance of immunosuppressed patients following liver transplantation is required.

General Surgery in Transplant Recipients

Following transplantation of an abdominal organ, surgical intervention on that organ should typically be performed by the original transplant team or another transplant team with extensive knowledge of the details of the operation. An understanding of both standard transplant vascular and enteric reconstructions as well as common variants (i.e., infrarenal aortic conduits for reconstruction of the hepatic artery) is required to avoid injury. If patient transfer is not possible, consultation with the transplant center is advised.

Abdominal operation is common following transplantation. A large center reported that 24% of liver transplant patients had another surgical procedure in the 10 years following transplantation.⁹³ Of patients who underwent elective procedures, the rate of complications and length of stay were not increased; however, following emergent procedures, this population experienced increased morbidity.⁹³ Common general surgery diagnoses are somewhat less common following transplantation. A review of over 8,000 patients following liver, heart, kidney, and pancreas transplantation revealed an appendicitis rate of 0.2%.⁹⁴ A review of over 4,000 liver transplant patients demonstrated small bowel obstruction in 48 patients (1.2%).⁹⁵ Etiologies included adhesions, internal hernias, volvulus, abdominal wall her-

nias, and neoplastic causes.⁹⁵ Internal hernias were most commonly related to residual mesenteric defects following construction of Roux-en-Y hepaticojejunostomy, whereas hernias around nonanatomic vascular reconstructions have also been reported.^{95,96} Long-term follow-up of 2,091 kidney transplant recipients revealed 12 patients with peritonitis from acute colonic complications, including diverticulitis, bowel ischemia, and perforation.⁹⁷ All surviving patients required operative intervention, most commonly as emergent laparotomy, although one patient died of diffuse colonic ischemia prior to exploration.⁹⁷ Aggressive medical management and early operative intervention are suggested when faced with transplant patients with peritonitis.

In general, immunosuppression is often decreased during episodes of significant infection or sepsis by either stopping agents or decreasing goal therapeutic levels. Perioperative management of steroids deserves special consideration. A series of kidney transplant recipients underwent operative procedures without stress-dose steroids with no evidence of adrenocortical insufficiency.⁹⁸ A review of renal transplant recipients who had lymphocele surgery similarly demonstrated no signs of adrenal insufficiency.⁹⁹ Wound complications and lymphocele recurrence were similar in both groups, whereas hyperglycemia was more common in the group that received stress-dose steroids.⁹⁹ In the absence of clinical signs of adrenocortical insufficiency, increased steroid dosing is not recommended in the perioperative period.

3 CLINICAL TRIAL DESIGN AND STATISTICS

Julie Ann Sosa, MA, MD, FACS

Definition and Overview of Study Design

A clinical trial is a planned experiment designed to prospectively measure the efficacy or effectiveness of an intervention by comparing outcomes in a group of subjects treated with the test intervention with those observed in a comparable group of subjects receiving another intervention.¹ The best clinical trials are randomized and double-blinded, but it is sometimes impractical or unethical to conduct them in clinical medicine and surgery. Conventional outcomes traditionally have been clinical end points; with the rise of new technologies, however, they are increasingly being supplemented and/or replaced by surrogate end points, such as serum biomarkers.²

Subjects can be animals or humans, but the focus of this chapter is on patients in actual practice as opposed to an ideal setting; therefore, effectiveness, rather than efficacy, is the appropriate metric. Because patients are involved, safety considerations and ethical principles must be incorporated into all phases of clinical trial design, conduct, data analysis, and presentation. Investigators cannot dictate what participants do during trial; they can strongly encourage compliance with protocol. Imperfect compliance must be anticipated, and accommodation must be made. As a result, clinical trials require investigators to assume significant responsibility and often consume significant human and financial resources.³

Three important principles separate clinical trials from other study designs and potentially afford them superiority of data quality and robustness of findings. First, all participants in a clinical trial must be followed forward in time from a well-defined starting point or baseline; this separates clinical trials from case-control studies, which can be retrospective. Second, interventions must be applied in a standard fashion across groups. They can be preventive, diagnostic, or therapeutic and can include drugs, devices, or procedures. By definition, clinical trials are experimental and not observational. Finally, a clinical trial must include a control group against which the intervention group is compared. A novel intervention can be compared with a current standard intervention or to no intervention at all (placebo).⁴ Participants in both groups can be on additional therapies and regimens other than those under study, but cases and controls should be as comparable as possible to facilitate teasing out the independent effect on outcomes of the intervention under study.⁵

History of Clinical Trials

The history of clinical trials has been best described by Bull and Lilienfeld.^{6,7} The fundamental underpinnings are ancient;

in the first Book of Daniel (verses 12 to 15), a planned experiment with a baseline assessment and follow-up is described:

Prove thy servants, I beseech thee, 10 days; and let them give us pulse to eat, and water to drink. Then let our countenances be looked upon before thee, and the countenance of the children, that eat of the portion of the King's meat: and as thou seest, deal with thy servants. So he consented to them in this matter, and proved them 10 days. And at the end of 10 days their countenances appeared fairer and fatter in flesh than all the children which did eat the portion of the King's meat.⁸

The first clinical trial with a concurrently treated control group involved 12 scurvy patients and was done in 1746 by Lind while at sea on board the *Salisbury*. Six dietary regimens were employed, and those seamen who received a daily ration of oranges and lemons fared best. In spite of the compelling trial results, the high cost of fresh fruit inhibited adoption of lemon juice for prevention of scurvy by the British Navy until 1795.⁹

Amberson introduced the concepts of randomization and blinding for treatment assignment in a clinical trial by using a coin flip to determine whether two comparable groups of patients with pulmonary tuberculosis received sanocrysin or distilled water in 1931; only the ward nurse and two of the investigators were aware of the treatments administered.¹⁰

The Nuremberg Code for Human Experimentation was issued in 1946 to address ethical issues surrounding the protection of human subjects. The first multicenter trials involved treatment of pulmonary tuberculosis with streptomycin and were published in the United Kingdom in 1948 and the United States in 1952. The Veterans Administration, together with the US Armed Services, continued multicenter trials for tuberculosis over the next two decades. The US poliomyelitis vaccine trials involved tens of thousands of volunteers and represented a significant increase in clinical trial scale. Creation of the National Cancer Institute in 1937 designated the start of federally sponsored medical research in the United States, which ultimately was recognized as the National Institutes of Health (NIH) in 1981.

A major stimulus for clinical trials in the United States arose from the Kefauver-Harris amendments of 1962 to the US Food, Drug and Cosmetic Act; they set forth legal requirements for "adequate and well-controlled investigations" that have to be satisfied before a drug can be approved by the Food and Drug Administration (FDA). In 1966, the US Public Health Service regulations leading to creation of Institutional Review Boards for research involving humans were published. In 1976, the Medical Device Amendments extended some of the testing requirements established for

drugs to medical devices as well. In the 1980s, Chalmers and colleagues led a movement to eliminate potential bias when physicians are permitted access to study data during the course of a clinical trial by separating patient care from treatment evaluation functions.¹¹

Clinical Trial Phases

Federal law requires that a drug be the subject of an approved marketing application before it is transported or distributed across state lines. Because a sponsor will probably want to ship the investigational drug to clinical investigators in many states, it must seek an exemption from the legal requirement. An Investigational New Drug (IND) application is the means through which the sponsor technically obtains the FDA exemption. There are three IND types: (1) an investigator IND is submitted by a physician who both initiates and conducts an investigation and under whose immediate direction the investigational drug is administered; (2) an emergency use IND allows the FDA to authorize use of an experimental drug in an emergency situation; and (3) a treatment IND is submitted for experimental drugs showing promise in clinical testing for serious or life-threatening conditions while the final clinical work is conducted and the FDA review takes place. INDs can be in commercial or research categories. Applications must contain information about animal pharmacology and toxicology studies, manufacturing information, and clinical protocols and investigator information [see Other Resources, below, for an Internet primer].

There are three phases of clinical trials. Phase I trials technically do not meet the criteria used to define a clinical trial. Nevertheless, they are necessary for showing that a novel intervention with promising preclinical data from in vitro and animal studies can be tolerated from a safety perspective in a small number of human patients. Typically, subjects already have tried and failed to improve on existing therapies and are willing to accept greater risk with potentially little or no benefit. The design is simple: a very small number of patients are exposed to escalating dosages of a novel drug to identify the maximally tolerated dosage (MTD) whereby intolerable side effects or precalculated pharmacokinetic safety levels are reached. There are also more sophisticated designs, whereby a sampling scheme using a step-up or step-down approach is employed, and a statistical model permits estimation of the MTD with a standard error of the mean.

Phase II trials are performed on larger groups of patients after the initial safety of a study drug has been confirmed. They are designed to continue to assess drug safety and dosing requirements but also to measure how well the drug works. When the development process of a new drug fails, it usually occurs during phase II.

The “classic” clinical trials are phase III studies, or randomized, controlled, multicenter trials on large patient populations that are aimed at being the definitive assessment of how effective a drug or other intervention is compared with the current gold standard treatment or even placebo if there is no standard of care. Because of their size and long duration, phase III trials are the most expensive and difficult trials to design and run. They can continue while appropriate regulatory agencies such as the FDA and/or the European

Medicines Agency (EMA) review the regulatory submission that combines animal and human study results, manufacturing procedures, formulation details, and shelf life.

Phase IV trials are known as postmarketing surveillance trials and represent safety surveillance and technical support for drugs after they receive permission from appropriate regulatory agencies to be sold. There is no control group in a phase IV trial. Rofecoxib (Vioxx) was removed from the market when harmful effects were identified in phase IV.¹²

Despite the fact that the FDA has quickened its review and approval of new medicines, clinical development is taking longer because of the complex nature of the diseases for which the new therapeutics are being created. The average time for the FDA to approve new drugs declined to 1.1 years in the 2005 to 2007 period, but the longer average clinical phase time means that the combined clinical and approval time is approximately 8 years.

Ethical Issues

Three general ethical principles guide clinical research. *Respect for persons* requires investigators to treat subjects as autonomous individuals, and they must obtain their informed consent to participate in the research project prior to any preparatory screening or intervention. The principle of *beneficence* requires investigators to design protocols that will provide valid and generalizable knowledge and ensure that the benefits of the research are proportionate to the risks assumed by the subjects. Finally, *justice* requires that the benefits and burdens of research are distributed fairly. In particular, disadvantaged, vulnerable, and minority groups (including racial and ethnic minorities, children, immigrants, disabled, and high medical need patients) should not be asked to bear a disproportionate share of risk in a trial.

Adherence to the principles of Good Clinical Practices (GCPs), including adequate human subject protection, is universally recognized as a critical requirement to the conduct of clinical trials involving human subjects.¹³ The Department of Health and Human Services has guidelines for human research. Risks to subjects must be minimized and proportionate to the anticipated benefits and knowledge. Data must be monitored to ensure the safety of subjects, and selection of subjects must be equitable. If subjects are vulnerable, additional safeguards should be included; for example, investigators must obtain both the permission of parents and the assent of the child when conducting research involving children. Institutional Review Board approval is required prior to screening and enrolling subjects.

Informed consent is required prior to screening patients for enrolment, and written consent forms are generally required. Informed consent must address the nature of the research project, including the purposes of the research, and the names and affiliations of the investigators. The procedures of the study must be described, along with how they differ from conventional care. Alternative procedures or treatments that may be available outside the study also should be discussed. Concepts of blinding and randomization should be explained in a simple, transparent fashion in simple language that is understandable.¹⁴

The potential risks and benefits of the study should be described, including their probability and magnitude. These

include medical, psychological, social, and economic ramifications. Assurances that participation in the study is voluntary should be provided because subjects must be able to withdraw from a trial at any time. Withdrawal cannot result in any penalty or loss of benefits. Protection of patient confidentiality and privacy must be guaranteed. Finally, investigators should offer to answer questions and provide further information if requested by potential subjects.

Randomized, blinded, clinical trials and placebo-controlled trials have unique ethical concerns. Reasonable people, and even experts, can disagree over the judgment regarding whether the null hypothesis can be rejected on the basis of previous evidence, which is the ethical basis for randomization. In addition, clinicians who believe that evidence already exists supporting use of one treatment alternative over another cannot justify enrolling patients if that treatment is available outside the trial. Analysis of preliminary data and interim analyses are essential for determining whether a trial should be stopped early, but such repeated analyses can undermine the power or validity of the study. In some situations, withholding active treatment from the control group can lead to serious complications, although this possibility is usually balanced by the possible hazards of active treatment. Also, blinding can cause problems in clinical management; for example, if a patient requires emergency surgery, the trial protocol must include a plan that permits unblinding in a rapid fashion, around the clock.

Investigators must realize that the different roles they play may create conflicts of interest. The Statement of Investigator Form FDA 1572 is a formalized agreement signed by the investigator to provide certain information to the sponsor and ensure that he or she will comply with FDA regulations related to the conduct of a clinical investigation of an investigational drug or biologic. An investigator who is also the personal physician for a study subject must appreciate that what is best for the patient's medical care may be in conflict with what is best for the clinical trial. Other problems can arise when the investigator has a financial interest in the therapy or procedure being studied; such interests always must be revealed in the consent and at the time of trial data presentation.¹⁵ Just the appearance of a conflict of interest can undermine research acceptance.

Implementing the Study

FORMULATING THE PROTOCOL FROM THE STUDY QUESTION

Clinical trials are ideally suited for trials of therapy for subjects with known diseases; this is what Alvin Feinstein called "remedial trials."¹⁶ Clinical trials are less well suited to studies of preventive measures because the outcome could be lengthy, and it might be impossible to keep subjects from being exposed to treatments that could impact the measured outcomes. They are also generally poorly suited for multiple therapeutic modalities, because too many subjects are needed to evaluate all of the treatment combinations, and for treatments with only rare outcomes or outcomes that are very far out in the future. As a result, clinical trials rarely produce good information about the adverse effects of therapies. Clinical trials should not be used to study therapies that may

be changed during the course of the study, such that the results of the study are obsolete prior to study completion. Finally, clinical trials are resource intensive, and, generally, their cost is not justified by the study of small changes in a therapeutic plan that will have a relatively small impact on clinical practice.

Defining the eligible population and selecting subjects from it before experimental or control status is assigned are essential.¹⁷ Development of the treatment protocol is predicated on asking a clinical relevant question; it must be easily replicable, capable of being "blinded," and resistant to drift or change during the course of the study. A major problem in many drug trials, for example, is that the dose of the drug must be adjusted to optimal serum levels or to obtain a visible clinical response, so a plan must be devised to allow for manipulation of the drug dose without giving away the fact that the patient is receiving the active agent or the placebo or alternative drug.

Selection of the alternative treatment(s) must be done with care, especially if it is a placebo. A crossover design is one in which subjects are exposed sequentially to both active treatment and a control or placebo intervention. This design is appealing in that subjects can serve as their own controls and might be more willing to enroll in a placebo-controlled study because they might be allowed to cross over to active treatment if they are initially assigned to the placebo and their condition progresses. Crossover studies have the potential to require smaller sample sizes than conventional parallel clinical trials, but not all interventions can be tested in this manner.

The two common plans for the design of clinical trials are either fixed- or variable-duration follow-up. In a fixed-duration follow-up trial, each patient is followed for the same prescribed period of time, regardless of when that patient entered the study. Fixed-duration trials are often employed to assess short-term objectives. Long-term studies employ variable follow-up duration, where patients are followed until a common closing date, regardless of when they were randomized. Regardless, the duration of follow-up should be based on the period of time needed to assess the trial's objectives and the frequency of follow-up visits on conventional clinical practice for the treatment and condition under study.¹⁸

Randomization is the best approach in the design of a clinical trial. It increases the likelihood that different treatment groups will be comparable in terms of variables that are recognized and measurable, as well as variables that are not affecting but still might affect outcomes. The randomization process can be modified in several ways. Blocked randomization ensures that the number of subjects is equally distributed among the study groups at periodic intervals during the process of randomization. Stratified blocked randomization ensures that an important baseline prognostic variable (associated with the outcome) is more evenly distributed between groups than chance alone would dictate; in so doing, it increases the power of a study by reducing variation in outcome that comes from chance. Finally, adaptive randomization uses a "biased coin" to alter the probability of assigning each subject to balance the distribution of baseline prognostic variables between study groups. Special analytical techniques other than the *t*-test and chi-square analysis should

be used for testing statistical significance with stratified block and adaptive randomization.

INCLUSION AND EXCLUSION CRITERIA

Specific clinical and demographic characteristics of the target population should be established and should be well suited to the research question. Inclusion criteria define the main characteristics of the target and accessible study populations. Exclusion criteria indicate subsets of individuals who meet the eligibility criteria but are likely to interfere with the quality of the data or interpretation of the findings. Exclusion criteria can improve the feasibility of the study at the cost of generalizability, so they should be used sparingly.¹⁹ Some exclusions are established by ethical considerations or by a patient's unwillingness to participate. Accessible populations can be clinic based or population based. Clinic-based samples are inexpensive and easy to recruit, but selection factors that determine who comes to the hospital or clinic may have an important and unwanted effect. Population-based samples are useful for guiding public health and clinical practice in the whole community, but this is more difficult to do and is much more expensive, particularly for relatively uncommon diseases.

PRETESTING AND QUALITY CONTROL

Pilot or feasibility studies should be conducted to pretest study methods as a study protocol should not be changed once the study has begun. These studies are useful for guiding decisions about how to design recruitment and measurement approaches. For example, pilot studies can provide estimates of the number of subjects who are likely to be available and willing to enroll and also can test the efficiency of different recruitment approaches. Finally, they can provide useful information about the age, gender, and demographic profile of the sample population.

MISSING DATA

Patients may agree to be randomized, but following randomization, they may not comply with the assigned treatment. Noncompliance may be overt or covert. When a subject overtly refuses to comply or outright stops participating in the study, the subject is called a dropout. However, a subject may just stop taking the agent under investigation without admitting this to the research team; this problem is more difficult to identify. Whenever possible, checks on potential noncompliance should be built into the study and could include regular pill counts for drug studies or urine tests for the agent under investigation or for one of its metabolites. Dropins are a more uncommon problem; they represent subjects who inadvertently take the agent assigned to the other group. This can occur when control patients take over-the-counter preparations of drugs under study without knowing it. It is important to anticipate noncompliance and dropouts or dropins in the study design as this will reduce any observed differences in the final analysis because the treatment group will include some subjects who did not receive the therapy. The size of the enrolled sample should be increased prior to the start of the clinical trial if noncompliance is an anticipated problem.

In the end, noncompliance and dropouts result in missing data, which should be anticipated prior to embarking on the

clinical trial to try to minimize the problem ($< 5\%$ of observations as a target), and an analytical method of dealing with the missing data should be anticipated. Options include (1) discarding data from all patients who did not complete the trial; (2) analyzing only the observed data; (3) using a single or multiple imputation to replace the missing observations with plausible values and then analyzing the "completed" data set; or (4) building a longitudinal model for the data, which includes a model for the dropout process. The technique "last observation carried forward" is a method whereby missing values are replaced by the last observed value of that variable; in so doing, it ignores trends in data and reduces variability in a somewhat arbitrary fashion. "Propensity scores" are classes of similar patients that represent more sophisticated imputation models; missing values are filled in by selecting randomly from observations in the same class of patients.²⁰

The fundamental efficacy data set includes all patients as randomized, regardless of protocol violations, withdrawals, and dropouts; this is called intent-to-treat (ITT). Modified ITT relaxes this to patients who have had at least one treatment.²¹ An alternative is the per-protocol data set, which includes only those subjects who had no protocol violations. In the end, it is important to examine the comparability of groups and outcomes and to provide various analysis data sets, especially given that the FDA and other regulatory agencies will expect to have access to all data and may audit a portion of it.

STANDARDIZATION, BLINDING, AND RANDOMIZATION

All clinical trials should employ a standard system of outcome evaluations in all patients randomized, such that judgments are unbiased and precise. To the extent possible, all trials should be double-blinded, meaning that neither the subject nor the investigator is aware of the treatment randomly assigned to the patient.²² Under no circumstances should the masking be violated, unless there is a serious adverse event. Complete double-blinding is impossible in some clinical trials, especially those in which a surgeon must know which procedure to perform. In this case, it is essential that outcome evaluations be masked at least to the evaluator. This is one reason that many trials employ a central laboratory or reading center for imaging studies (e.g., using Response Evaluation Criteria in Solid Tumors [RECIST]).²³ As much as possible, standardization of evaluation using manuals and definitions of normal versus abnormal or stabilization versus progression or partial response of disease to treatment should be ensured.

PLANNING FOR DATA MANAGEMENT, MONITORING, AND AUDITS

Prior to embarking on a clinical trial, data entry, editing ("cleaning"), and analysis should be anticipated. Planning for data management begins with developing rules for coding the variables for computer entry. The appropriate hardware and software programs should be selected and standardized across study sites. Software can include spreadsheet programs, database managers, and/or statistical or graphics programs. All data should be backed up, and storage should be secure and password protected, with access limited to recognized members of the investigational team.²⁴

To facilitate quality control of data management, prior to the start of the study, a decision should be made to be parsimonious with data collection. Forms for data collection should be precoded and self-explanatory. They should be coherent and clearly formatted, easy to read, pretested, and validated, and every page should be labeled with a date, name, and identification number for the protocol. In large studies, it is useful to have a quality control coordinator who is a member of the research team and/or an external monitor whose responsibility it is to check data entry against source documentation. For large collaborative trials, a governance system with a steering committee made up of the principal investigators with subcommittees should be formed, and a coordinating center with central review (i.e., for evaluation of radiologic studies) should be established to facilitate communication, data entry, and analysis.²⁵

INTERIM ANALYSES

Periodic tabulations and reports should be issued to ensure that missing, inaccurate, or imprecise measurement is not a significant problem. Experiments that administer drugs in a blinded fashion, in particular, require special attention to quality control. In addition, clinical trials that employ laboratory procedures require ongoing attention to labeling and blinding; in this setting, it can be useful to also use blinded duplicates or standard pools.²⁶ In drug trials, in particular, reports describing significant adverse events and unanticipated drug toxicities should be issued concurrent with their occurrence, such that if there is a need to modify the protocol or the informed consent based on a changing safety profile, it can be done in a timely fashion to maintain patient safety.

Interim analyses should be specified a priori in the protocol. They are essential for several reasons: (1) examining the safety of an intervention at an early time to ensure that subjects are not being harmed; (2) examining efficacy at an early time (i.e., the study should stop if the intervention is very good or very bad); and (3) reestimating sample size (if variability is too large or treatment effect is too small, sample size might need to be increased). However, care should be taken when performing interim analyses because they carry the risk of unblinding.

RESEARCH TEAM AND OTHER TRIAL PRAGMATICS

Members of the research team should be selected carefully. There should be a formal system for training staff who will carry out measurements of importance and for testing and certifying their competence to do so. Often there are basic competencies and certifications that are required by Institutional Review Boards, the NIH, sponsors, or other governing bodies, and these should be kept current and on file in a regulatory binder. Accountability is essential, and a system of supervision should be clearly outlined; this same system should be employed to provide performance review. From the earliest planning phase, the investigator should lead a series of regular meetings with all members of the research team.

Before embarking on a clinical trial, it is important to ensure that funding is adequate to support it to conclusion. Virtually all funding groups require a budget and justification as part of a research proposal if grant support is solicited. Administrative staff should be consulted to provide needed

information for calculating budget needs to ensure that the final product conforms to regulations and is also a realistic projection. Categories of expenses that should be considered include personnel, consultant costs, equipment, supplies, travel, patient care costs, alterations and renovations, consortium or contractual costs, and other expenses. These are all direct costs. Indirect costs are generally calculated as a percentage rate that is applied to the anticipated direct cost budget that will cover the departmental or organizational administration costs that each clinical trial program should bear.

For personnel, each staff member's name, position, function, hours/week, or percent effort with salary and fringe benefits should be described. Subcontracting can be a useful mechanism for minimizing the cost of research activities that require special skills that are not readily available from existing staff. Research costs for clinical trials also can be minimized by using existing data collected for other purposes and by incorporating research tasks in the ongoing responsibilities of existing staff. A contract should be negotiated with the assistance of legal counsel; no change in study objective, scope, or methods can be made prior to explicit funding agency approval.

Generally speaking, as few changes to the protocol as possible should be made after the clinical trial has begun as they will affect analysis and, ultimately, interpretation of study results.

Basic Biostatistics for Data Analysis

Biostatistics is a specialized field that is critically important to planning, conducting, and interpreting the results of a clinical trial.²⁷ A brief overview of broad principles and an introduction to the basic lexicon of fundamentals will be provided, but this is not a substitute to undergoing formal training in the discipline or to having a trained biostatistician serve as a member of the clinical trial research team.

HYPOTHESES AND UNDERLYING PRINCIPLES

A study should begin with a good hypothesis based on a good research question; the hypothesis can be simple or complex, but it should be specific and without ambiguity. It should be stated in writing at the outset of the study. Hypotheses are classified by the way they describe the anticipated difference between study groups. The null hypothesis states that there is no association between the predictor and outcome variables; it is the formal basis for testing statistical significance. The proposition that there is an association is called the alternative hypothesis; it cannot be tested directly and is accepted by exclusion.

A one-sided (or one-tailed) hypothesis specifies the direction of the association between the predictor and outcomes, whereas a two-sided (or two-tailed) hypothesis asserts only that an association exists and does not specify the direction. A one-sided hypothesis permits a smaller sample size than a two-sided hypothesis but is sometimes inappropriate for application.

TYPE I AND II ERROR

A type I error (false positive) occurs if an investigator rejects a null hypothesis that is actually true in the population. A type II error (false negative) occurs if the investigator

fails to reject a null hypothesis that is false in the population. Neither of these errors can be avoided entirely, but their likelihood can be reduced by increasing the sample size of the study population for the trial; that is, the larger the sample size, the less likely it is that it will differ significantly from the population.

The likelihood that a trial will detect an association between a predictor and an outcome depends, in part, on the actual magnitude of that association in the population. Unfortunately, the actual magnitude of the association is usually not known. Therefore, the investigator must choose the size of the association that he or she would like to be able to detect in the sample; this quantity is known as the effect size. Choosing an appropriate effect size is the most difficult aspect of sample size planning. Data can be used from the literature or from pilot studies when there are no data to support an estimate. Usually, it is wise to choose the smallest effect size that would be clinically meaningful.

The probability of committing a type I error is called α (alpha), or the level of statistical significance. The probability of making a type II error is called β (beta). The quantity $(1-\beta)$ is called power, or the probability of observing an effect in the sample if one of a specified effect size or greater exists in the population. Many studies set α at 0.05 and β at 0.20 (a power of 0.80). These are somewhat arbitrary values, and others are sometimes used: the conventional range for α is 0.01 to 0.10 and for β between 0.05 and 0.20. Sample size planning aims at choosing a sufficient number of subjects to keep α and β at an acceptably low level without making the study unnecessarily expensive or difficult to perform.

The p value is the probability of obtaining the study results by chance if the null hypothesis is true. The null hypothesis is rejected in favor of its alternative if the p value is less than α , or the predetermined level of statistical significance. Nonsignificant results (i.e., with p values greater than α) do not imply that there is no association in the population; rather, they mean that the association observed in the sample is small compared with what could have occurred by chance alone. Because an alternative hypothesis has two tails, either or both can be tested in the sample by using one- or two-tailed statistical tests, respectively. When a two-tailed statistical test is used, the p value includes the probabilities of committing a type I error in each of the tails, which is twice as great as the probability in either tail alone. Conversion from one- to two-tailed p values is easy; for example, a one-tailed p value of .05 is identical to a two-tailed p value of .10. Unnecessary use of two-tailed hypotheses increases the sample size needlessly, but some statisticians and journal editors insist on their use in all situations.

Variability of effect (in addition to size of effect) is an important statistical consideration. The greater the variability (or spread) in the outcome among clinical trial subjects, the more likely it is that the values in the groups will overlap, and the more difficult it will be to demonstrate a difference between them. When variables are dichotomous, variability is included in other parameters entered into the sample size formulation and does not need to be specified. When one of the variables is continuous, however, its variability needs to be estimated.

Variables that are not the subject of study in a trial can confound the apparent association between the predictor and

outcome under study. In general, analytical approaches that adjust for confounding variables will increase the required sample size. A rough approximation can be made by increasing the sample size by 10 to 20% for each major confounder.

Finally, in advance of a trial, it is important to establish as many hypotheses as make sense but to specify one as the primary hypothesis to provide a clear basis for the main sample size calculation. In addition, a single primary hypothesis can be tested statistically without argument about whether to adjust for multiple hypothesis testing. One controversial but stringent approach to multiple hypotheses testing (Bonferroni) is to divide the significance level (e.g., .05) by the number of hypotheses tested; this can substantially increase the anticipated sample size of the trial.²⁸

ESTIMATING SAMPLE SIZE AND POWER

A t -test is used to determine whether the mean value of a continuous outcome variable in one group differs significantly from that in another group. It assumes a normal (bell-shaped curve) distribution of the variable in the two groups. A z statistic can be used to compare the proportion of subjects in each of two groups in a clinical trial who are expected to have a dichotomous outcome. The z statistic resembles the chi-square test, except that it can be one- or two-tailed, whereas the chi-square test is always two-tailed.

To summarize, the steps in estimating sample size for a clinical trial are the following:

1. State the null hypothesis and a one- or two-tailed alternative hypothesis.
2. Select the appropriate statistical test based on the predictor and outcome variables employed in the hypotheses.
3. Choose a reasonable effect size and variability.
4. Set α and β .
5. Use a standardized table or calculator, some of which are available on the Internet or in biostatistics manuals, to estimate sample size.

Often there is insufficient information for estimating sample size; this is especially true when a clinical trial includes a study sample that has not previously been examined. In these situations, an extensive literature search from previous findings on the topic should be conducted.²⁹ Other investigators in the field should be contacted for their judgment regarding reasonable expectations, or a pilot study could be conducted. Dichotomization of a variable can be helpful. When all else fails, an educated guess can be made to yield a reasonable estimate.³⁰

STRATEGIES FOR MINIMIZING SAMPLE SIZE

When continuous variables are an option, they permit a smaller sample size than dichotomous variables. For example, measuring blood pressure in millimeters of mercury (mm Hg) (continuous) rather than as the presence or absence of hypertension (dichotomous) permits a smaller sample size for a given power. When the outcome is dichotomous, using a more frequent outcome is a good way to increase power because power depends more on the number of outcomes that occur than it does on the number of subjects in the study. The number of outcomes, in turn, can be increased by extending the follow-up period, liberalizing the definition of

what makes up an outcome, and enrolling subjects at higher risk for developing the outcome.

More precise variables permit a smaller sample size because they reduce variability. Techniques for increasing the precision of a variable, such as making measurements in duplicate, require that more resources be put into measurement and may require that resources be taken away from other aspects of the trial, such as recruitment. Generally speaking, fewer measurements on more subjects is a good rule for study planning. Use of paired measurements, with one at baseline and another at the end of the study, often permits a smaller sample size because it reduces variation of the outcome variable, which is the change between these two measurements. A *t*-test is used to compare the mean value of the change in the two groups. Finally, use of unequal group sizes in a clinical trial can be helpful for increasing power; in general, the gain in power when the size of one group is increased to twice the size of the other is considerable, whereas tripling or quadrupling one of the groups provides progressively smaller gains.

STATISTICAL TESTS OF SIGNIFICANCE

Descriptive statistics should be provided based on data gathered about the baseline demographic and clinical characteristics obtained for subjects in the study. The most basic analyses carried out are bivariate; these are tests of the relationship between an independent variable and a dependent variable, or outcome. Statistical tests in which normal distributions of data are assumed are parametric tests; if both independent and dependent variables are numerical, a Pearson *r* correlation coefficient can be reported, which is derived from the process of linear regression. It is an estimate of the relationship between the two variables. If the data are not normally distributed, they may need to be transformed or nonparametric tests (e.g., ranked correlation tests, such as Kendall or Spearman correlation) employed.

When the association between a numerical dependent variable and a categorical independent variable needs to be measured, a *t*-test can be performed. The *t*-test is also appropriate if the dependent variable is categorical and dichotomous and the independent variable is numerical. In some clinical trials, patients may serve as their own controls, in which case, a paired *t*-test is needed. When the independent or dependent variable is categorical but has more than two categories, an analysis of variance (ANOVA) is used.

When both the independent and dependent variables are categorical, a chi-square test is performed based on a two by two table. The chi-square test is very sensitive to sample size. For small samples where the expected value for any cell is less than 5, a Fisher exact test should be used instead of the chi-square.

After the investigator performs a series of bivariate analyses, it is often necessary to deal with potential confounding variables. This can be done either with stratification or multiple regression analyses. In stratification, the investigator tests for the association between independent and dependent variables in subsamples that have been stratified in terms of the potential confounding variable. Multiple regression tests for the association between two variables while simultaneously controlling for other variables; linear regression is used when the dependent variable is continuous; and

logistic regression is used when the dependent variable is categorical.

RELATIVE RISK

In medical research, relative risk (RR) has become one of the standard measures. It is expressed as the risk ratio in randomized, controlled trials and cohort studies, whereas odds ratios are favored for case-control studies and retrospective studies. RR, or risk ratio, is the risk of an event (or of developing a disease) relative to an exposure; it is a ratio of the probability of the event occurring in the exposed group versus the nonexposed group. It is amenable to logistic regression modeling, typically in a Poisson regression framework.³¹ A relative risk of 1 means that there is no difference in risk between the two groups, whereas an RR less than 1 means that the event is less likely to occur in the experimental group than in the control group, and an RR greater than 1 means that the outcome is more likely to occur in the experimental group than in the control group.

SUBGROUP ANALYSES

A subgroup analysis is sometimes undertaken to assess treatment effects for a specific patient characteristic; the assessment is often listed as a primary or secondary study objective. Alternatively, it is undertaken to investigate the consistency of the trial conclusions among different subpopulations defined by each of multiple baseline characteristics of patients. However, the reporting of subgroup analyses has been problematic and inconsistent. It should always be revealed whether the subgroup analyses were prespecified or were performed post hoc, and the potential effect on type I errors attributable to multiple subgroup analyses and how this effect was addressed in the data analysis should be described. When multiple subgroup analyses are performed, the probability of a false positive finding can be substantial.³²

Heterogeneity of treatment effects across the levels of the baseline variable refers to the circumstance in which the treatment effects vary across the levels of the baseline characteristic. The appropriate statistical method for assessing the heterogeneity of treatment effects among the levels of a baseline variable begins with a statistical test for interaction. Many trials lack the power to detect heterogeneity in treatment effect. Therefore, the inability to find significant interactions does not show that the treatment effect seen overall necessarily applies to all subjects. Common mistakes are to claim heterogeneity on the basis of separate tests of treatment effects within each of the levels of the baseline variable and to claim heterogeneity on the basis of the observed treatment effect sizes within each subgroup, ignoring the uncertainty of these estimates. When possible, analyses of the heterogeneity of treatment effects should be based on tests for interaction and should be presented along with effect estimates (including confidence intervals) within each level of each baseline covariate analyzed. A forest plot is an effective method for presenting this information. Overinterpretation of subgroup differences should be avoided as much as possible.

Other Resources

A useful resource for patients and for investigators is www.ClinicalTrials.gov, a Web-based registry of federally and

privately supported clinical trials conducted in the United States and around the world. The NIH-sponsored Web site gives information about each trial's purpose, who can participate, locations, and telephone numbers for more information. In addition, the FDA (www.fda.gov) includes the Center for Biologics Evaluation and Research (CBER), which is responsible for evaluation of biologics (i.e., cellular/gene therapy products, tissue/tissue products, allergenics, blood/blood products, and vaccines); the Center for Devices and Radiological Health (CDRH), which is responsible for evaluating surgical implants and prosthetics, personal protective equipment, LASIK and radiation-emitting products; and the

Center for Drug Evaluation and Research (CDER), which reviews the evaluation of new drugs prior to their going to market. The CDER offers a pre-IND application consultation program to foster early communication between sponsors and new drug review divisions to provide guidance on the data necessary to warrant IND submission. A useful resource on the Internet is <http://www.fda.gov/Drugs/DevelopmentApprovalProcess/HowDrugsareDevelopedandApproved/ApprovalApplications/InvestigationalNewDrugINDApplication/Overview/default.htm>.

4 EVIDENCE-BASED MEDICINE

Emily R. Winslow, MD

Descriptions of “evidence-based” approaches to medical care are now ubiquitous in both the popular press and medical journals. The term *evidence-based medicine* (EBM) was first coined in 1992, and over the last two decades, the field has experienced rapid growth, and its principles now permeate both graduate medical education and clinical practice.¹ To be clear, the field has been in constant evolution since its introduction and continues to undergo refinements as its principles are tested and applied in a wide variety of clinical circumstances.

Brief History of Evidence-Based Medicine

Although the term *evidence-based medicine* is relatively new, the first recognized randomized controlled trial (RCT), which examined the treatment of pulmonary tuberculosis, was published in 1948. In addition, several other seminal documents paved the way for modern-day clinical trials: the publication of the Nuremberg Code in 1947 and the Declaration of Helsinki in 1964, which established ethical codes and principles of protection of human subjects in clinical research. The first well-known RCTs studying surgical interventions were published in 1964. One of these examined surgical treatments for duodenal ulcer, and the other examined the survival benefits of portocaval shunt surgery in cirrhotic patients.^{2,3}

One of the earliest and most important figures in the modern-day EBM movement was Archie Cochrane, who practiced in Wales and authored the influential book *Effectiveness and Efficiency: Random Reflections on Health Services* in 1972.⁴ He emphasized the importance of the RCT as a means to determine the most effective therapies so that health care resources could be more equitably distributed. In 1992, 4 years after his death, the opening of the first Cochrane Centre in Oxford, United Kingdom, marked his important contributions to the field. A second seminal figure in the field was Alvan Feinstein, who is now recognized as one of the founders of modern-day clinical epidemiology. As the founding director of the Robert Wood Johnson Foundation Clinical Scholars program at Yale University, he contributed importantly to the field of clinical research methods, coining the term “comorbidity” and describing the now well-known “Will Rogers phenomenon.”

Perhaps the most widely recognized name in the field of EBM is David Sackett, who established Canada’s first department of clinical epidemiology and biostatistics at McMaster University in Hamilton, Ontario. His many accomplishments include his important role in the education of clinicians in understanding modern-day clinical evidence and applying its principles to the care of patients, as best illustrated by the book *Evidence-Based Medicine: How to Practice and Teach*

EBM.⁵ Furthermore, he founded the University of Oxford’s Centre for Evidence-Based Medicine (CEBM) in 1994, the world’s first center for EBM.

Evidence-Based Medicine: Fundamental Tenets

DEFINITION

EBM has been commonly defined as the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients.⁶ EBM also emphasizes the integration of the best available evidence with clinical expertise and patient preferences. Much emphasis has been placed on defining the best available sources of evidence, usually described in the form of evidence hierarchies. However, the founders of EBM specifically envisioned this evidence being integrated into the framework of clinical decision making.

CLINICAL DECISION MAKING

Clinical Expertise

The importance of clinical expertise cannot be overestimated because without this, the evidence, no matter how good its quality, cannot be properly applied. The skills of physical examination, development of a differential diagnosis, and evaluation of a symptom complex must be mastered before external evidence can be applied to an individual patient. Furthermore, comorbid conditions and other limitations that may affect the patient’s ability to undergo a particular therapy (e.g., financial constraints, difficulties with compliance, and geographic logistics) must be assessed before selecting the most appropriate therapy for an individual. Sackett and colleagues described the interdependence of clinical expertise and evidence well: “Good doctors use both individual clinical expertise and the best available clinical evidence, and neither alone is enough. Without clinical expertise, practice risks being tyrannized by evidence... Without current best evidence, practice risks becoming rapidly out of date.”⁶

Patient’s Values and Preferences

An evaluation of the patient’s values and preferences is the third and perhaps most essential component of EBM. This requires that the clinician understand and incorporate the value that an individual patient would place on a given outcome and on a given risk. The patient’s perspectives on the time required, cost incurred, and expected change in symptoms must be appreciated for a decision to be rendered. This is clearly the most difficult aspect of the practice of EBM, and no one method of assessing and integrating each patient’s values has been established.

EVIDENCE HIERARCHY

Examples of Evidence Hierarchies

To establish the relative strength of evidence for clinicians, hierarchies of clinical study designs have been formulated. These pyramidal structures have been popularized by many groups and have undergone evolution as EBM has matured. The hierarchies currently used most frequently include those from the Evidence-Based Medicine Working Group [see Table 1] and the CEBM [see Table 2 and Table 3]. The Evidence-Based Medicine Working Group revised its initial hierarchy and published the current version in 2000.⁷ The CEBM is currently seeking comment on its updated version. Importantly, these hierarchies have been simplified here to include only those levels of evidence specific for treatment trials. Studies looking at diagnostic accuracy, prognosis, harms, and screening require a separate analysis and are not discussed.

Rationale behind the Hierarchy

It is important to recognize that despite the widespread acceptance of this evidence hierarchy, the rationale behind the ordering of these systems has not been as clearly delineated. It is often assumed that because randomization controls for all confounding factors, it would eliminate bias attributable to confounders. Although randomization does

Table 1 Strength of Evidence for Treatment Decisions (Evidence-Based Medicine Working Group)⁷

1. *n*-of-1 randomized trial
2. Systematic reviews of randomized controlled trials
3. Single randomized controlled trial
4. Systematic review of observational studies with patient-centered outcomes
5. Single observational study with patient-centered outcome
6. Physiologic studies
7. Unsystematic clinical observations

Table 2 Oxford Centre for Evidence Based Medicine Levels of Evidence⁶¹

Level	Therapy/Prevention/Etiology/Harm
1a	Systematic review with homogeneity of randomized controlled trials
1b	Single randomized controlled trial with narrow confidence interval
1c	All or none studies
2a	Systematic review with homogeneity of cohort studies
2b	Individual cohort study and low-quality randomized controlled trials
2c	"Outcomes" research
3a	Systematic review with homogeneity of case-control studies
3b	Individual case-control studies
4	Case series (and poor quality cohort and case-control studies)
5	Expert opinion, physiology studies, bench research

Table 3 Oxford Centre for Evidence Based Medicine Revised Levels of Evidence⁶²

Level	Treatment Benefits
1	Systematic review of randomized trials or <i>n</i> -of-1 trials
2	Randomized trials or observational studies with dramatic effect
3	Nonrandomized controlled cohort/follow-up study
4	Systematic review of case-control studies, historically controlled studies
5	Opinion without critical appraisal, mechanistic studies

Caveat: The level may be graded down on the basis of study quality, imprecision, indirectness, inconsistency between studies, or small absolute effect size. The level may be graded up if the effect size is large.

eliminate statistical bias as it applies to the entire sample space, this requires a trial to be repeated indefinitely. With any particular allocation (i.e., one RCT within the entire sample space), the probability of any one confounder being unequally balanced between groups is high. Only in the very unpractical indefinite sequence of randomized trials will the effect of unbalanced confounders be negated, eliminating statistical bias.⁸

The most compelling argument to date is that the hierarchy is based instead on comparative internal validity: a measure of how likely the results of any given study are to be true for the subjects involved. One essential method of ensuring internal validity is to ensure that the control of the allocation of patients into treatment groups does not lie with the investigator. This is best accomplished by randomization but can also be achieved by other study designs that are prospective and experimental.⁸

It is important to emphasize that although internal validity is essential to properly interpret the results of a given clinical trial, it is not sufficient for the application of the trial's results to a variety of patient groups. This is the domain of external validity, which refers to how well the results can be applied to patients unlike those randomized in the study. In fact, those conditions that enhance internal validity usually serve to decrease external validity. The lack of generalizability is not addressed by the evidence hierarchy and remains a challenge for EBM.

Evolution of the Hierarchy

Although evidence hierarchies were an important tool in the field's development, they have now been largely supplanted by the use of systems to grade the strength of a body of evidence, which is discussed below. A further development along these lines is the addition of a new hierarchy that guides users with respect to most efficiently locating high-quality evidence, coined the "4S" approach⁹ [see Table 4]:

1. In this conception, the most efficient way to access evidence is from a well-designed system. These systems are not currently well developed but would ideally provide a concise summary of all the available high-quality evidence and apply it directly to a given clinical scenario. At present, these systems can offer much less, but there are nevertheless some options for an integrated approach, such as the *British Medical Journal's* Clinical Evidence system.

Table 4 “4S” Approach to Finding Resources for Evidence-Based Medicine⁹

Type of Resource (in descending order)	Example
1. Systems	Decision support tools in EMRs, <i>BMJ Clinical Evidence</i>
2. Synopses	<i>ACP Journal Club</i> , DARE
3. Syntheses	Cochrane Reviews, other systematic reviews
4. Studies	Medline Clinical Queries, Cochrane Central Register of Controlled Trials

EMR = Electronic Medical Record.

- When no system is well developed enough to provide adequate guidance, the reader is directed toward synopses. These take the form of structured abstracts summarizing high-quality evidence and providing further context and commentary that will help the reader understand the limitations of the data presented. The best known example of this at present is the *ACP Journal Club*.
- Syntheses represent a third level of access to evidence and are represented largely by systematic reviews that collate all available evidence on a given topic. The popular Cochrane reviews epitomize these syntheses, although multiple other groups have produced similar high-quality systematic reviews.
- Individual studies are the foundation of all the previously listed levels and by themselves can supply all the same information. However, this means of access to the medical literature is inefficient because the reader must not only be able to identify the relevant primary studies but must also be able to proficiently appraise them. Although it is important for each clinician to possess these skills, it is not always feasible in a limited amount of time to use primary studies as the first-line approach to the medical literature.

Critical Appraisal of a Single Study

At the core of the basic tenants of EBM is undoubtedly the ability to critically appraise a single study. The basic skills required for critical appraisal apply to all study types, but the specific considerations vary. Here we consider the central tenants of critical appraisal as they apply to the types of studies most commonly reviewed by surgeons: RCTs, observational studies, and systematic reviews of each [see Table 5 for a summary of the text below].

ANALYSIS OF A RANDOMIZED CONTROLLED TRIAL

Although the principles behind the analysis of an RCT are not complicated, the literature surrounding the assessment of their quality certainly is. In 2002, the Agency for Healthcare Research and Quality (AHRQ) undertook an evaluation of all available systems that rated the quality of evidence.¹⁰ At that time, nearly 50 separate tools were available to evaluate RCTs. Because there is currently no universally accepted tool for analyzing the quality of a RCT, we provide a summary of the considerations that appear in most of the commonly employed systems.^{11–14}

Assessment of Internal Validity

The first priority in analyzing any RCT is to determine the degree to which the results of the study are accurate for the sample of patients included in the study. This is the most essential component of critical analysis. To ensure that the results are valid, the following components should be assessed.

Randomization and its concealment Concealed randomization ensures that the treating clinician’s subjective impression of the patient’s state of health and likelihood of benefiting from the experimental treatment do not influence the patient’s chance of receiving that therapy. Taking the allocation out of the hands of clinicians is essential to the avoidance of selection bias that can result in fundamentally different groups at baseline. Well-concealed and truly randomized designs serve to increase the likelihood that the treatment and control groups will be similar in terms of important prognostic factors at the trial’s outset.

Blinding and its effectiveness Three separate groups should be assessed for the adequacy of blinding: the subject, the clinician, and the outcome assessors. If the subject is aware of the treatment group, it is clear that this may influence both subjective and objective outcomes. The subjects in the treatment arm may benefit from the placebo effect if they are aware of their assignment, whereas those in the control group (ironically getting the placebo) will not. Furthermore, the treating clinician may alter the other treatments (called cointerventions) that a patient receives based on his or her assessment of the effectiveness of the intervention. This introduces a type of performance bias and may well affect the results of the trial. The assessors of the outcome of interest should also be blinded to the treatment group assignment to prevent the possibility that it will affect the more subjective outcome measures, so-called detection bias. This is perhaps both the easiest and the most important group to blind in an RCT.

Equivalence between treatment groups Although randomization is intended to minimize the differences between treatment groups in terms of baseline characteristics, this is not a guaranteed result, especially with smaller sample sizes. It is therefore essential to gauge the success of the randomization by comparing the groups at baseline with respect to known prognostic factors. Ensuring that the unknown prognostic factors are equally distributed is simply not possible and remains a source of concern, but the likelihood will increase with increasing sample size. It is also important to maintain equivalence between the treatment groups throughout the study period by treating them identically in all ways except for the treatment under study. This includes, among other things, additional visits to the clinic, diagnostic tests, or other therapeutic changes.

Completeness of follow-up Even if there is well-concealed randomization with effective blinding and equivalent treatment groups, incomplete follow-up can significantly jeopardize the validity of an otherwise well-conducted RCT. This is because there is generally not a random pattern to the occurrence of dropout, and it must be assumed that it could be related to the treatment itself, its side effects, or other

Table 5 Critical Appraisal of Individual Studies Examining Therapeutic Decisions

Type of Study	Important Aspects to Consider in Critical Analysis (see text for detailed explanation)	Examples of Representative Quality Assessment Tools
Randomized controlled trial	Randomization and its concealment Blinding and its effectiveness Equivalence of treatment groups Completeness of follow-up Accuracy of analysis Magnitude and precision of treatment effect Generalizability of findings	Oxford's CEBM critical appraisal sheet ¹¹ Cochrane handbook's tool for assessing bias ¹² Sackett and Guyatt's users' guide for articles about therapy ¹³
Systematic review of RCTs	Importance of question Appropriateness of search Explicitness of inclusion criteria Validity of included studies Homogeneity of included studies Reproducibility of results	Oxford's CEBM critical appraisal sheet ¹⁵ Sackett and Guyatt's users' guide for summarizing the evidence ¹⁶ BMJ's "How to read" a paper series ¹⁷
Observational study	Rational creation of treatment groups Baseline comparability between groups Reliability of data collection Adequacy of follow-up	MINORS assessment tool ¹⁸ University of Cambridge's quality domains ¹⁹ AHRQ's description ²⁰ NHS Health Technology Assessment's a priori criteria for quality ²¹
Systematic review of observational studies	Completeness of search Assessment of study quality Similarity of studies in combined analyses	

AHRQ = Agency for Healthcare Research and Quality; CEBM = University of Oxford's Centre for Evidence-Based Medicine; MINORS = Methodological Index for Non-randomized Studies; NHS = National Health Service; RCT = randomized controlled trial.

related variables. A systematic difference in withdrawals between groups is described as attrition bias and can significantly impact the trial's results. To determine the likelihood of a substantial change in outcome, the worst-case scenario with all subjects lost to follow-up having the undesired outcome should be computed.

Accuracy of analysis Provided that all the above features have been satisfied, the last step is to ensure that the results are properly analyzed. Perhaps the most essential component in this area is that the final analysis compares the originally randomized groups rather than the treatment groups that result during the conduct of the study. This is essential because the crossover from one group to another is usually reflective to some degree of the treatments being compared. This is especially true in surgical trials, where patients who are particularly ill and randomized to surgical arms may end up crossing over to the nonsurgical arm, likely enhancing the surgical group with respect to baseline prognosis. This is referred to as an analysis by intention-to-treat (ITT) and is essential to maintaining a lack of selection bias. Another important aspect of analyzing the trial's results is to ensure that outcomes have not been reported selectively. This can be done by looking at the primary and secondary aims specified in the clinical protocol, which is now readily available by requiring the registration of clinical trials prior to inception. In addition, the methods of analysis and planned subgroups can also be examined to ensure that there has not been significant reporting bias.

Assessment of External Validity

Because a study's results may be accurate for the patients enrolled, this in no way implies that a recommendation for a change in therapy should automatically result. Instead,

it must also be determined that the trial results are both important and generalizable.

Assessing the importance of results For the result of the trial to change practice, it must have an effect of sufficient magnitude. The measurement of a therapy's effect can be reported in many ways, but many EBM groups have advocated that the number needed to treat (NNT) be an important component. This allows the clinician to determine the significance of any given relative risk reduction by considering the number of patients who would need to be treated to prevent one bad outcome. This must necessarily be weighed against the adverse effects of the treatment. Further discussion assessing the magnitude and precision of treatment effects is beyond the scope of this chapter but can be found in many sources of EBM.¹⁴

Assessing the generalizability of results To determine if the trial results can be applied to a particular patient, the clinician must determine if the randomized patients are sufficiently similar in terms of disease severity, comorbid conditions, and willingness to comply with therapy. Furthermore, the treatment as administered in the trial must be feasible for both the patient and the health care system. Most importantly, the patient's values and preferences must be considered to determine if the benefits of the new therapy outweigh the inconvenience, cost, and perceived harms for each patient.

ANALYSIS OF A SYSTEMATIC REVIEW OF RANDOMIZED CONTROLLED TRIALS

Although the systematic review of RCTs is usually placed near the top of an evidence hierarchy, this does not imply that this methodology ensures high-quality evidence. In fact, because of the weight placed on this type on analysis, it is of

particular import that clinicians understand how to critically appraise their content. As with individual RCTs, there is no uniformly accepted quality assessment tool for assessment, but the following considerations are generally accepted in most evidence-based medicine schemas.^{15–17}

Quality of the Search Process

The most essential step in the production of a high-quality systematic review is the conduct of the literature search. To ensure that all eligible studies are available for analysis, this process must be thorough, careful, and unbiased.

Importance of the clinical question To have the systematic review be useful to clinicians, the precise clinical question to be answered during the process of the search must be clearly stated. This is often formulated in a prescribed way, often described by the acronym PICO (population, intervention, comparison, and outcome).¹⁵ It is important to explicitly define these variables to ensure that the search process includes all the relevant studies but does not include ones that will not address the specific clinical question being posed.

Appropriateness of search strategy Because the goal of a systematic review is to systematically include all the relevant primary data, the search strategy must be deliberately thorough and organized. It should be described explicitly enough that it could be reproduced. It is important that all available and relevant databases were used and that studies were not unnecessarily excluded as a result of narrowness of the search strategy. The citations of all identified studies should be systematically reviewed (ancestral searching). Furthermore, the inclusion or exclusion of “gray literature” should be described, as should the use of unpublished reports and registries.

Explicitness of criteria for study inclusion The criteria used to include or exclude a study from inclusion in the systematic review should be clearly defined, uniformly employed, and clinically reasonable. This will help decrease the possibility that the reviewer’s bias about the desired conclusion will affect the studies selected. These criteria should describe the specifics of the population to be studied, the intervention(s) that addresses the clinical question, the outcome measures of interest, and the range of acceptable study designs.

Quality of the Analytic Process

Once the comprehensive search has been completed and the relevant studies have been identified, the details of the analytic process will then determine the quality of the evidence that will be produced.

Validity of the included studies In addition to ensuring that the studies meet the criteria for inclusion, it is important for the internal validity of the individual RCTs to be separately assessed. It has been previously suggested that each trial be weighted according to quality, but because no validated method of accomplishing this has been produced, it has become preferred instead to provide an analysis of the quality of each study according to its ability to maintain internal validity.

Homogeneity of the included studies It is also important to have an assessment of the similarity of results between studies, a characteristic referred to as homogeneity. If there is significantly more heterogeneity than expected by chance, it is important to determine if methodological differences in the included studies that would account for the variability exist. However, if significant unexplained variability remains, the clinician should be skeptical about the appropriate application of the review’s conclusion.

Reproducibility of results Because there are many variables in the conduct of the search and the analysis that can significantly impact the review’s outcome, it is essential that the conclusion be reproducible. This is often addressed by having multiple reviewers involved in the systematic search and extraction of the data so that systematic bias is minimized. Furthermore, the concept of conducting a sensitivity analysis of the results has been proposed. This entails making minor systematic changes in the analysis of the data (such as exclusion of low-quality studies, inclusion of only the most recently published reports) to determine if the results of the analysis are robust enough to remain the same. If, instead, the analysis is sensitive to such minor variations, its results should be questioned and implemented only with caution.

ANALYSIS OF AN OBSERVATION STUDY

Although the critical assessment of RCTs follows fairly well-accepted principles, the analysis of the quality of an observational study is the subject of much debate. Some of the proponents of EBM have routinely discounted observational studies as being poor quality a priori given their non-randomized design. Although there is certainly some truth to that position, the fact remains that for the vast majority of clinical questions, the only evidence available comes from nonrandomized observational studies. This is particularly true for surgical disciplines. Therefore, it seems important that any reader of the medical literature be able to adequately assess the quality of observational studies. Some of the general principles discussed by multiple groups are described below.^{18–21}

Rational Creation of Treatment Groups

The central criticism of observational studies is that they are, by their very nature, biased in the assignment of patients to the treatments being compared. If the treating clinician willfully assigns some patients to one treatment and others to another, there is frequently a difference in demographic or prognostic variables between groups. It is therefore essential for the reader to clearly understand by what means the treatment groups were created. This includes a description of the larger group from which the subjects of the report were chosen and the specific factors related to the patient’s health status that led to the choice of the treatment selected. For example, it should be stated if the patients in the treatment group were selected by the acceptance of locally recognized inclusion criteria (i.e., practice patterns), by patient preference after being given multiple options, or by a wholesale change in practice with the introduction of a new therapy. A detailed description will help the reader assess if there was significant confounding by indication.²⁰ Similarly, defining how the comparison group was selected and if the groups were treated contemporaneously is also informative.

Baseline Comparability between Treatment Groups

As stated above, the comparison of nonrandomized groups should always be approached with caution. Whatever method has been used to select the treatment groups, it is important that the reader be able to objectively compare them with respect to essential baseline characteristics. The relevant prognostic features, demographic information, and diagnostic evaluation should be clearly compared. Factors that may not be well known to the reader but are clearly different between treatment groups should be explicitly considered by the authors. Examples of this type of consideration include a difference in geographic distribution (e.g., those living locally receive one treatment preferentially, whereas those who must travel usually receive another), choice of treating clinician (e.g., patients who see one clinician are offered one therapy as a default, whereas those seeing another clinician are routinely offered a different therapy), and economic considerations (e.g., patients with supplemental insurance received the more expensive therapy, whereas those with less economic assistance received the other alternative).

Reliability of Data Collection

Given that the groups being compared in observational studies may be different from one another, it is important to ensure that the data collection is as reliable and unbiased as possible. This includes explicitly stating the following:

- Were the data collected prospectively, retrospectively, or in a mixed fashion?
- Were the specific outcome measures explicitly defined and systematically collected and by whom?
- What sources of information were used to determine if the outcome occurred and to which was priority assigned if a discrepancy existed?
- Was the assessment of the outcome made with knowledge of the participant's treatment group?

Adequacy of Follow-up

As with RCTs, the length and completeness of follow-up are essential to assessing the quality of an observation study. It is important for the following to be detailed:

- The length of the follow-up period in each group and the distribution of the range of follow-up lengths
- The specific method by which the patient was followed: regular interval versus sporadic, telephone call versus clinic follow-up, symptomatic versus routine testing
- The number of patients in each group lost to follow-up, a description of their baseline characteristics, and an estimation of the likely reason for attrition

ANALYSIS OF A SYSTEMATIC REVIEW OF OBSERVATIONAL STUDIES

In general, the analysis of a systematic review is similar in nature, regardless of whether the included studies are RCTs, observational studies, or a combination of study types. However, those reviews that include observational studies encounter some unique challenges.²²

Completeness of Search

Because observational studies are not specifically catalogued by search engines, the details of the search strategy

must be explicit and must include significant redundancy. The criteria for study inclusion must be particularly complete and topic specific.

Assessment of Study Quality

Because of the difficulty in assessing the quality of an observational study in general, it is difficult to incorporate quality assessment into a systematic review. It is, however, essential that some description of each study's quality be given so that the reader can be assured that the level of evidence being used to compare treatment groups is roughly equivalent.

Similarity of Studies Combined in Analysis

Observational studies may have differences in design so profound that it is simply unreasonable from a clinical perspective to combine their results in any meaningful way. The reader of systematic reviews must therefore view some of these reviews as a descriptive and hypothesis-generating exercise. This is in contrast to the quantitative combination of RCTs in a meta-analysis.

Reporting Guidelines for Single Studies

It is important to recognize that the quality of a study's design and conduct is a wholly separate consideration from the quality of its reporting. It is plausible to assume that there is some association between these two measures of quality, but they are not directly related and should be assessed separately. Fortunately, there are now several well-publicized guidelines for the reporting of particular types of trials that will be enumerated below. Many journals are now using these in the process of manuscript review and are therefore gaining popularity.

The name and year of the last update of the most widely recognized tools are listed in Table 6. These tools each provide a checklist for reviewers in addition to a document that more thoroughly explains the rationale and the implementation of the checklist.²²⁻²⁶

The advantage of standardized reporting guidelines is that they require that the design and conduct of the study and its subsequent analysis be explicitly described. Elements of a study's conduct that are not ideal cannot simply be omitted if the expectation is that all items on a given checklist will be entertained by the authors. A second advantage is that studies can now be more reliably assessed for their inclusion in a systematic review. Finally, it is likely that as more attention is

Table 6 Reporting Guidelines by Study Design

Type of Study Design	Reporting Guidelines	Last Update
Randomized trials	CONSORT ²³	2010
Systematic reviews and meta-analysis	PRISMA ²⁴ (formally QUORUM)	2009 1999
Observational studies	STROBE ²⁵	2007
Meta-analysis of observational studies	MOOSE ²²	2000
Studies of diagnostic accuracy	STARD ²⁶	2003

being paid to the quality of reporting, an improvement in the quality of a trial's design and conduct will follow.

Critical Appraisal of a Body of Evidence

When compared with the evaluation of a single study, the critical appraisal of a larger body of evidence has many more challenges. The foundation of any particular body of evidence fundamentally rests on the critical appraisal of each study. However, making an adequate assessment of an entire body of evidence is difficult and requires consideration of additional elements that need not be considered for an individual study.

GRADING OF EVIDENCE AND MAKING OF RECOMMENDATIONS

In considering a body of evidence, two separate types of conclusions can emerge. The first and most obvious is a summary statement (a “grade”) of the overall assessment of the quality of the body of evidence. This, in general, takes into account the types of study designs, the consistency of results between studies, and the applicability of the available evidence to the clinical question. On the contrary, “recommendations” are not simply a reflection of the grade of the evidence being summarized but instead reflect an evaluation of the quality of the overall evidence in context. Because the varying weight placed on these broader considerations is quite subjective and will not be separable from the viewpoints of the recommenders, summary recommendations should be carefully evaluated by the reader. The primary data on which they are based should be considered in the context of values and preferences when making a clinical recommendation to a particular patient.

Evolution of Grading Systems

As EBM has gained popularity, there has been a proliferation of schemas by which a body of evidence can be evaluated. These have been useful in helping the reader to understand the type of evidence on which a recommendation is based. Unfortunately, because of the multiplicity of systems currently in use, it is no longer clear to the reader what is meant by “level 1” evidence as this can be variably described in the literature with different combinations of Roman numerals, letters, and words. Because of the resultant confusion in the literature, several groups have attempted to popularize a single system that could be employed universally.

Specific Systems Used to Grade a Body of Evidence

Although more than 25 systems to evaluate a body of evidence have been described,¹⁰ the discussion here is limited to three separate examples to illustrate the diversity being employed.

GRADE system In 2000, an informal international collaboration began that evolved into the Grading of Recommendations Assessment, Development and Evaluation (GRADE) Working Group. This was largely pioneered by Gordon Guyatt from McMaster University but includes many well-known international experts. This group's goal was to create a system to grade the strength of a body of evidence that could be easily employed and understood by a diverse group of

authors and readers and that would accurately reflect the quality of the underlying evidence.²⁷

Strength of evidence grade This group has created a system the grades the evidence quality using the following: high-, moderate-, low-, or very low-quality evidence. This is based primarily on the quality of the study design, consistency of effect between studies, generalizability of the outcomes from each study to the population of interest, and effect size as reflected in the measurement of the odds ratio, relative risk, or hazard ratio.

Recommendation grade The GRADE system further characterizes recommendations dichotomously, as strong or weak. In considering the strength of a recommendation, four factors are emphasized: the quality of the evidence, the balance between the benefits and harms, the consideration of variability of values and preferences of the population at hand, and, finally, a consideration of whether the intervention represents a wise use of health care resources.

Examples in practice The GRADE system has been widely employed and is accepted by several important stakeholders, making it arguably the leading classification. For example, the *British Medical Journal (BMJ)* and its EBM publication *Clinical Evidence* both request use of the GRADE system. Other groups using GRADE include the Cochrane Collaboration, the World Health Organization, the American College of Physicians, and UpToDate. In addition, the American Thoracic Society, one of the leading surgical groups focused on EBM, has endorsed the GRADE system.

The SORT system The Strength of Recommendation Taxonomy (SORT) system was developed by the editors of major US family medicine and primary care journals and was published in 2004.²⁸ This system was designed to be uniform and straightforward enough that primary care physicians could readily use it in daily practice.

Strength of evidence grade The grades assigned in the SORT system are levels 1 through 3. These are based on the following essential features: if the outcome is patient oriented, the quality of the reported evidence base, and the consistency of the findings.

Strength of recommendation grade Recommendations in the SORT system are categorized as A through C. Features considered in the recommendation grade are the consideration of patient-centered outcomes, the quality of the underlying evidence, and, interestingly, the grading of the recommendation by other groups.

The AHRQ system The Comparative Effectiveness Reviews published by the AHRQ reviewed the systems for grading evidence in 2002, and it immediately became clear that a number of systems of variable quality were being used to grade the quality of evidence and to make recommendations of varying strengths. The value of having a uniform system was recognized, and a system was designed for the evidence-based practice (EPCs) systems that they supported.²⁹

Strength of evidence grade The levels of strength in this system include high, moderate, low, and insufficient. The guiding principles used to determine the grade in this system are primarily risk of bias, consistency, directness, and precision. The GRADE system can be used by the EPCs as well

so that a more quantitative approach can be employed when needed.

Strength of recommendation grade Interestingly, this group explicitly avoids the making of recommendations because its members view their purpose as proving the information on which decision makers can make recommendations. Given that the EPC reports are used by a wide spectrum of agencies and societies with different priorities and goals, the aim was to create summaries of the evidence with an evaluation of their quality so that recommendations could then be drawn from those data in the context of the values of the group making the recommendation.

CENTRAL TENANTS TO APPRAISING A BODY OF EVIDENCE

Formulating a “Grade” for a Body of Evidence

Although many different systems exist that can help specific groups apply similar principles and arrive at consistent grades for bodies of evidence, these can best be understood by considering the central tenants employed by the majority of systems. These are similar to those employed in the appraisal of a single study but include additional considerations that help deal with the issues that arise by trying to combine a multiplicity of studies.

Evaluating the risk of bias Perhaps the most important characteristic of a body of evidence is its overall susceptibility to bias.

Study design This assessment includes consideration of both study design and conduct. Having several well-controlled, blinded, RCTs will clearly help assure the reader that there is a relatively low risk of bias. However, even in the absence of RCTs, the overall risk of bias can still be quite low. This can occur, for example, with observational studies where the effect of the treatment on the disease state is obvious (so-called “all or none” effects) or those that have a dramatic effect size.

Reporting bias In addition to the particular study design, the possibility of reporting bias should be considered. When only a few studies are available and all show some marginal benefit, it should be carefully considered whether those that showed some marginal harm have not been considered because of the failure to be included in the published literature. This can be ascertained by examining the registry of RCTs, comparing the study protocol with the reported study results, and talking to experts in the field involved with review of manuscripts for publication.

Quantity In estimating the risk of bias, it is helpful to have an understanding of the total number of patients who have been studied and the number of separate groups and/or institutions that have conducted the studies of interest. At the extreme, one RCT with a limited number of patients from a single institution is much more likely to be susceptible to bias than is the evidence culled from a large number of studies from multiple institutions. Although no absolute number should be used, an estimation of the quantity of data points should be explicitly stated.

Evaluating consistency between studies Even if the studies being considered have a low risk of bias, there is no guarantee that their results will necessarily be consistent.

Direction of effect An evaluation of the direction of the effect measured should be considered first. If some studies show harm, whereas others demonstrate benefit, this clearly raises concern for consistency. Evaluators of the evidence should look carefully to try to determine if such inconsistency can be explained by differences in populations selected, details of the treatment employed, or biologic differences in the disease under study. If such an explanation appears rational and accounts for the differences, the evidence can still be considered consistent. If not, then the overall assessment of the quality of evidence is lowered. Statistical tests of heterogeneity can be employed if meta-analysis is appropriate (e.g., Cochrane’s Q test of I^2 statistics) but are not necessary to determine the overall consistency of a body of literature.

Evidence of dose response When a clear difference in effect size can be seen with different doses of the treatment under study, the biologic principle of a dose-response curve bolsters the validity of the data.

Evaluation of a single study When only a single study is available, consistency cannot be assessed. Even with a large, well-designed trial, the fact that only a single study exists precludes any evaluation of consistency.

Evaluating generalizability of study results Even if high-quality and consistent evidence is available, it is critical that it be applicable to the study question. This is often referred to as “directness” and can be viewed as a measure of how obviously the available evidence applies to the patient being treated.

Patient-oriented outcomes One important consideration is the specific outcome measured by the evidence. Surrogate outcomes are those that do not represent the actual outcome of interest but rather more intermediate and mechanistic outcomes. For example, the ability of a particular orthopedic procedure to improve radiographic findings but not the symptom complex would be an example of indirect evidence. In addition, the outcome being evaluated need not only have a direct link to the evidence but must also be one that is of interest to the patient. These include measures such as morbidity, mortality, quality of life, and symptom relief but not improvement in laboratory values, degree of pathologic response, or tumor measurements.

Directness of comparisons When comparing multiple treatments, the directness of the comparisons between each treatment should be assessed. The idealized comparison would be between each treatment separately within the same study. Because this is rarely possible, the reader is often comparing treatment 1 with treatment 2 in one study and treatment 2 with treatment 3 in another, with no direct evidence comparing treatments 1 and 3. Although some comparisons can be made by way of effect size and consistency of outcomes, this evidence must still be judged as indirect.

Assessing external validity To determine if the results of a body of evidence can be applied to a given patient, it must be determined that the patient was adequately represented in the population under study. For example, if high-quality and consistent evidence exists that shows treatment A results in improved quality of life, but the majority of participants in the study were more than 65 years old, it cannot be assumed that this same treatment will have identical effects on a younger patient population.

Evaluating the effect size The strength of the association between treatment and effect should be considered. The effect size can be measured in many different ways but is commonly reported as an odds ratio, a relative risk, or a hazards ratio.

Assessing the magnitude of the effect The magnitude of the effect size refers to absolute change in the risk or likelihood of the outcome of interest before and after a particular treatment or exposure. Although there is no evidence for a particular magnitude of effect that is acceptable, the GRADE group has used effect sizes of more than 5 and less than 0.2 as most significant and those of more than 2 and less than 0.5 as of lesser significance.²⁷

Assessing the precision of the effect In addition to the absolute magnitude of the effect, the relative precision of the pooled effects is also important. This reflects the degree of certainty surrounding the estimate of effect and is measured by the pooled confidence interval. The narrower the pooled confidence interval, the easier it is to estimate the effect seen so that it may be more reliably compared with the effects of other treatments. Should the pooled confidence interval be so wide that it includes both the possibility of benefit and of harm, no conclusion about the effect can be rendered.

Formulating a Recommendation

The formulation of a recommendation from an assessment of the quality and strength of a body of evidence seems at first to be straightforward. However, this process ultimately requires that values be assigned to relative benefits and risks, costs, convenience, and system-wide issues. The process of making recommendations is therefore quite subjective, and the procedures, values, and interests of the group making the recommendations should therefore be carefully explored before simply accepting the level of recommendation made.

The strength of a given recommendation should include an assessment of the overall quality of the evidence. Clearly, a strong recommendation should not be made on the basis of weak evidence. Furthermore, recommendations should consider the balance of the desirable and undesirable effects of any particular treatment. For example, the negative effects of chemotherapy on quality of life, symptoms, and even fertility should be weighed against the benefit of extension of life or prolongation of disease-free interval. These types of judgments are difficult enough for a given patient and physician to make together but are nearly impossible to determine on the population level. This is because the values and preferences of the individual patient are undoubtedly variable, making a summary statement at times impossible.

The difficulties in making recommendations also include issues surrounding the value that the system should place on given outcomes relative to their costs. This dilemma is central to the debate over health care in general and cannot be simplified in any given recommendation. Some interventions will result in effects that are profound enough and of low enough cost that there is little room to debate their merits. Those decisions about interventions that have either modest effect but high costs or minimal effects irrespective of cost warrant the majority of the discussion.

Evidence-Based Surgery

Although EBM has been maturing over the last 20 years, the field of evidence-based surgery has been slower to develop.

In fact, the idea of evidence-based surgery has frequently been derided. For example, an editorial in 1996 written by the editor of the *Lancet* was entitled “Surgical Research or Comic Opera: Questions, But Few Answers.”³⁰ A more recent example of the fairly broad-based disdain for evidence-based surgery is the presentation given by the editor of *BMJ* in 2004.³¹ The title of the presentation given in 2004 was “Is Surgery an Anachronism in an Evidence Based Age?”³¹ These statements from prominent advocates of EBM illustrate significant questions about the state of evidence-based surgery today and the challenges that it faces moving forward.

HISTORY

Although the first RCTs in surgery were published in 1964, the popular application of the RCT to surgical therapies has been quite slow. For example, in a systematic review of the literature from 1966 to 2000, Wentz and colleagues found that only 15% of all published clinical trials dealt with surgical issues.³² Furthermore, of all the articles published in the five leading surgical journals, only 3% were RCTs. Of these, about half did not deal directly with surgical therapy but rather issues of medical therapies in surgical patients. Although there was a significant increase in the number of surgical RCTs from the 1960s to the early 1980s, the number appears more stagnant from the 1980s to 2000.

Several recent developments have been important steps in the development of evidence-based surgery. In 2000, under the leadership of Samuel Wells, the American College of Surgeons Oncology Group (ACSOG) was established and given responsibility for studying the surgical treatment of cancer. The group became one of nine cooperative clinical trial groups funded by the National Cancer Institute and has now initiated about 30 multiinstitutional trials of surgical therapies. Similar central organization of surgical resources has occurred internationally as well. The German Surgical Society established a center for the German study of surgery, known as the SDGC, in 2005. Furthermore, the Royal Australasian College of Surgeons has established the Australian Safety and Efficacy Register of New Interventional Procedures—Surgical (ASERNIP-S), which began in 1998. This group does not sponsor clinical trials but does serve to produce systematic reviews of surgical topics and help identify areas of innovation in surgery when RCTs may be best applied.

CHALLENGES TO EVIDENCE-BASED SURGERY

As the slow uptake of the RCT into the field of surgical research empirically demonstrates, there are inherent challenges to the execution of RCTs in surgical disciplines.^{33,34} These are enumerated below.

Methodological Issues

Difficulty with standardization One of the fundamentals in the execution of a RCT is that all the participants are treated similarly. When compared with the administration of medicines, the delivery of surgical care is much more difficult to standardize.

Technical variability Between individual surgeons, there is a wide array of technical skill and experience. Although key components of an operative procedure can be specified, it is

difficult to specify and monitor the degree of skill with which these steps are executed. Furthermore, pre- and postoperative care introduce additional variables that are difficult to standardize and likely introduce confounders.

Effect of the learning curve When new procedures or methodologies are introduced, it has clearly been demonstrated that a learning curve exists. The shape of this curve differs by procedure, and there is currently no well-accepted method for predicting in advance the shape of the curve. This clearly introduces variability into any RCT that includes a new procedure or technology and biases the results in favor of the older therapy with which the operators are more familiar.

Evolution of a procedure Even after the learning curve has reached a plateau, surgical procedures continuously evolve by iterative change. Technical modifications to the procedure itself, the postoperative care pathways, and the preoperative selection criteria are constantly occurring but are not easily measured objectively.

Difficulties with placebo control One of the major differences between a surgical therapy and a medical therapy is the ease with which placebo controls can be instituted. Because a surgical procedure itself is known to have a clear placebo effect, it can be important for trials of surgical therapy to include a placebo arm. However, the issue of sham surgery for the benefit of research purity has ignited much debate. Given the Common Rule's insistence on fundamental principles of risk minimization and the balance between risks and potential benefits for the subjects, there are clear ethical challenges to the use of surgical placebo arms.

Difficulties with blinding Although it is possible to blind the clinician prescribing therapy in a trial involving medical treatment, it is not possible to blind the surgeon who performs a surgical procedure to the type of procedure he or she is to perform. Further, it can be difficult to blind patients to the type of surgical procedure performed because there can be differences in associated incisional discomfort or side effects known to occur only with one arm of the trial.

Feasibility Issues

Assuming that the methodological issues could all be dealt with in some way, additional barriers still exist to the conduct of a surgical RCT.

Difficulties with recruitment Although surgical RCTs have been successfully completed, many have suffered from difficulties with recruitment. There are several potential reasons for this. It is clear that patients have strong feelings with regard to their willingness to undergo a surgical procedure and that these are magnified when patients are asked to consider being randomized to either a medical or a surgical therapy (e.g., chemotherapy or surgical excision of a tumor) or to one of two fundamentally different surgical procedures (e.g., continence-preserving procedures or procedures that entail creation of an ostomy). Even if a group of amenable patients could be assembled for an RCT, doubt about the external validity of the trial would still remain given that the majority of patients might have refused enrolment. The patient's unwillingness to participate has been identified as the most common reason for nonentry into surgical RCTs.³⁵

For example, when asked about their willingness to participate in a hypothetical RCT comparing vaginal delivery with elective cesarean section, only 14% of pregnant women indicated that they would participate.³⁶ Such a low level of willingness to participate in an otherwise reasonable RCT is clearly a problem for investigators trying to study surgical therapies.

Lack of equipoise Once a new surgical therapy has been developed and standardized to the point at which it is appropriate to study in a large-scale clinical trial, collective clinical equipoise may no longer be present. It has also been suggested by some that because it is routinely necessary for effective surgeons to make important clinical decisions rapidly in the face of limited data, they are as a group by nature and/or training less capable of having the ambivalence necessary for clinical equipoise to exist.³⁷

Interest in rare outcomes Because surgical therapies are often compared on the basis of complication rates, it can be difficult to have a study that is adequately powered to look at rare events of harm. For example, one of the most relevant outcomes for liver surgery is the rate of postoperative mortality, which generally occurs at a rate of about 1%. One group has calculated that to have an adequately powered study in liver surgery to answer the question of whether a particular technique changes the rates of postoperative death would require enrolling more than 15,000 patients.³⁸ Given that only about 7,000 liver resections are performed annually in the United States, it is unlikely that this volume could be accrued in a reasonable period of time.

Lack of funding Because of the requirement of the Food and Drug Administration (FDA) for evidence from RCTs for new drug applications, the pharmaceutical companies trying to bring these drugs to market are obligated to conduct and, usually, to fund these trials. This experience with drug trials has helped establish the infrastructure of clinical trials at many centers and is the basis on which they fund their clinical research efforts. Interestingly, there is no agency similar to the FDA for surgeons.³⁹ Although it is clear that surgical therapies can inflict as much harm on patients as can medical ones, there is no governmental body that protects patients from surgical interventions. Because of the lack of a requirement for RCTs for surgical procedures and devices, there is little motivation and, consequently, industry funding for surgical trials. Although some progress has been made in this area, the extraordinary cost of a surgical RCT that may require the labor-intensive process of teaching and monitoring the procedures of all surgeons involved is at times viewed as prohibitive.

Lack of oversight Similarly, the lack of a body overseeing the approval of new surgical therapies has left them currently in the domain of experimental therapies. Should a given surgeon participate in a clinical trial and the patient experience harm as a result of an unproven therapy, some physicians are concerned about the possibility of malpractice litigation in this setting.⁴⁰ This added concern and the lack of universal procedures for dealing with legal matters in the conduct of clinical trials serve to further decrease the feasibility of RCTs in surgery.

ISSUE OF THE OBSERVATIONAL STUDY

Introduction to the Problem of Observational Studies

The place of the observational study in the field of EBM has been a contentious topic. As evidence hierarchies began to be popularized, there was clear recognition of some of the limitations of nonexperimental observational studies. There was concern about the fact that observational studies are more vulnerable to certain biases than randomized studies, and some have even gone so far as to advocate that observational studies should not even be considered by the reader.

Although the concerns about the validity of observational studies are rational, it cannot be disputed that they continue to represent the vast majority of the evidence available in many fields. If only data from RCTs were considered, it would be difficult to make any rational clinical decisions about the vast majority of clinical questions that arise on a daily basis, particularly in surgical fields. To simply discount the value of observational studies completely would be flippant. However, the use of data generated from the observational study must be cautiously incorporated into clinical decision making.

Evidence to Support the Difference between RCTs and Observational Studies

One of the arguments central to the controversy over the utility of observational studies is how their results have compared with the outcomes of RCTs. The discussion often centers on several notable examples of how observational studies led to the widespread acceptance of therapies that were later demonstrated in RCTs to be harmful. Two prominent examples frequently given to support the fallacies of observational studies are the effect of hormone replacement therapy on myocardial infarction in postmenopausal women and the use of certain antiarrhythmics to prevent sudden death after myocardial infarction. These are clear examples of how observational data can be misleading, but the question as to the frequency with which they do so remains.

Perhaps the most comprehensive analysis of this topic was sponsored by the United Kingdom's National Health Service and was published in 2003.²¹ This review looked carefully at eight separate studies published that compared the results of observational studies with those of randomized ones. The authors concluded that these studies as a whole were inconclusive given difficulties with metaepidemiologic methodology but suggested that they all supported the claim that observational studies are sometimes, but not always, biased. Importantly, in this analysis, 82 clinical topics were included, only four of which were primarily surgical topics.

However, since that time, at least three separate analyses have compared the results of surgical observational studies with those of randomized ones. The first of these compared RCTs with observational studies in the field of digestive surgery.⁴¹ The authors found that only 25% of the time did the observational studies give different results than RCTs. A second study compared the results of studies of open and laparoscopic cholecystectomy and concluded that the results differed in at least 20% of outcomes and that the observational studies had significantly more heterogeneity.⁴² A final study examined these two study types in the comparison of laparoscopic and open resection of colorectal cancer and found that the results were remarkably similar.⁴³ This study

included only studies coming from a recent era that were published at a similar time, suggesting that this may be a more accurate type of comparison.

It can certainly be concluded that the observational study has certain limitations when compared with the RCT. However, at least in surgical disciplines, the evidence to date suggests a reliable but not constant relationship between the outcomes of observational studies and RCTs. It would therefore behoove the surgical community to continue to increase the number of questions being answered by RCTs but also to simultaneously work on improving the design and reporting of observational studies. Some progress along these lines is already being made, but this field continues to be in its infancy.⁴⁴

Current Place of the Observational Study in Surgery

Importantly, when the scientific objective is to detect and measure a small but clinically important difference between two therapies, the standard should continue to be a well-designed and executed RCT. However, because of some of the issues that differentiate surgical from pharmacologic studies, the observational study will likely continue to be a significant part of the evidence base in surgical disciplines.⁴⁵ This is most reasonable in the following situations:

- When ethical considerations prevent the use of a surgical placebo arm
- When the unwillingness of patients to be randomized to two radically different therapies prevents adequate accrual in an RCT
- When the rare effects of different therapies, particularly harms, are to be compared
- When the need to examine the generalizability of a given therapy to a broader population is paramount

POTENTIAL SOLUTIONS FOR EVIDENCE-BASED SURGERY

Although significant challenges confront investigators when conducting surgical trials, many of these issues can be addressed by novel strategies that will allow the quality of surgical research to continue to improve. The study of the adaptations necessary for surgical trials is still in its beginning stages but will likely continue to be fruitful as surgeons continue to push forward in the field of evidence-based surgery.

Some Solutions to Methodological Issues

Standardization Although it is difficult to standardize a surgical procedure, several groups have demonstrated that with significant effort, a group of surgeons can be taught to perform a given step in a procedure with reasonable similarity (e.g., total mesorectal excision for rectal cancer). This can be accomplished by standardized training and, importantly, real-time mentoring during a designated number of procedures. Further, the requirement for routine assessment of intraoperative videos or photographs and standardized assessment of the pathologic specimens can further enhance our ability to standardize a surgical RCT. It should be noted that this type of effort requires a significant investment of resources and should be undertaken only when the technique of the procedure itself is central and performed with significant enough variability to reasonably impact outcomes. In addition, the use of preliminary studies, termed phase II surgical studies (or phase IIS), has been advocated as a means to test methods

of surgical quality, to practically define the relevant end points, and to more accurately estimate the sample size needed for phase III studies.³⁷

Placebo control Ethical concerns around surgical placebo controlled trials have been addressed by the Council on Ethical and Judicial Affairs of the American Medical Association.⁴⁶ This document provides some guidance in this arena and suggests a basis on which the appropriateness of a surgical placebo arm can be evaluated. These considerations include the feasibility of no other trial design, the susceptibility of the outcome in question to the placebo effect, and small risks associated with the surgical placebo arm.

Blinding Although the surgeon cannot be blind to the treatment group, it is possible at times with careful technique to blind the subject. Further, the assessors of the outcome measures of interest can be blinded to the treatment group, decreasing the likelihood of introducing bias by the absence of blinding.

Some Solutions to Feasibility Issues

Recruitment Because patients' preferences can clearly influence their willingness to enter randomized trials, patient preference arms conducted alongside an RCT (often called comprehensive cohort designs) have been investigated and represent a potentially useful adjunct to surgical trials.⁴⁷ The development of tools that aid in decision analysis strategies may help patients better understand their own preferences and choices.

Equipoise To address the issue of equipoise on the part of the surgeon, a novel trial design termed "expertise-based randomized controlled trials" has been suggested.⁴⁸ This strategy randomizes patients to clinicians with expertise in one or the other treatment arms. This has several advantages as it removes the learning curve from consideration, allows each group of surgeons to treat patients similarly, and resolves the issue of clinical equipoise in the sense that a given surgeon does not need to perform the procedure that he or she feels is inferior. It does, however, require some collective sense of equipoise on behalf of the larger community.

Rare outcomes Because of the concern for harmful but rare outcomes from the introduction of surgical innovation, a group of thought leaders in the field, termed the Balliol Collaboration, has begun to define the process by which surgical innovation should be evaluated.⁴⁹ This group emphasizes that different considerations need to be entertained at different stages of innovation (known as the IDEAL paradigm). Such a framework is useful for surgeons as they consider the introduction of new procedures and how to safely monitor rare outcomes outside of the confines of a typical RCT.

Solutions to Bias in the Observational Study

A much more complex topic is how the approach to the observational study can be modified in such a way as to allow more valid evidence to result. One suggestion has been to develop a variety of nonrandomized study designs that would allow for nonexperimental studies but decrease the elements

of bias. Others have suggested that we simply reject the idea that judgments made together by patients and their surgeons are too complex to be quantitatively understood and instead focus on ways in which these confounders could be more reliably measured. This sentiment was stated well by Lantos: "Rather than constraining human choices to meet the needs of statisticians, I think we should encourage statisticians to devise methods of evaluating the source of choices that free and intelligent citizens make all the time."⁵⁰ It is clear that new methodologies that account for the known confounders in observational studies would help encourage progress in surgical fields as they would allow for improved recruitment into studies, decreased costs, and more generalizable results. The ability to more accurately account for confounding variables in observational trials would serve to further our knowledge in the areas of surgical care where RCTs are not needed.

RESOURCES FOR EVIDENCE-BASED SURGERY

Given the relatively new interest in evidence-based surgery, there are still a limited number of EBM resources that focus on surgical issues. These are, however, growing in number, and new resources continue to appear. However, those EBM resources that have focused primarily on medical issues contain relevant information for many surgical topics. See Table 7 for a list of some of the helpful resources currently available.

Limitations in Evidence-Based Medicine

SITUATIONS IN WHICH RANDOMIZED CONTROLLED TRIALS ARE NOT USEFUL

All-or-None Situation

In response to what was felt to be a dogmatic insistence on evidence from RCTs, a group from the University of Cambridge in 2003 wrote the now classic article in the *British Medical Journal* entitled "Parachute Use to Prevent Death and Major Trauma Related to Gravitational Challenge: Systematic Review of Randomised Controlled Trials."⁵¹ In this brief but pointed piece, the authors demonstrate clearly one of the major limitations of EBM: its exuberant application of RCTs to any clinical problem. The authors demonstrated that there were no RCTs of parachute use and that the data to support their use were purely observational and suggested that those who feel that RCT data are needed should be participants in the trial. This satire provoked reasoned discussion about the limitations of EBM. This situation wherein the treatment effect is dramatic enough not to raise the specter of the effect of bias has been termed the "all-or-none" criterion. Even the proponents of EBM readily recognize that in similar situations, an RCT is not only unnecessary but unethical.

Large Treatment Effects

One way of thinking about treatment effects that are dramatic in nature is to consider the outcome of the treatment ("signal") relative to the expected outcome without treatment ("noise").⁵² It has been proposed that if the signal-to-noise ratio is greater than 10, the likelihood of bias being responsible for the purported effect of the treatment is unlikely

Table 7 Key Resources for Evidence-Based Surgery

Resource	Features	Relevance to Surgery
Cochrane Collaboration Database of Systematic Reviews Database of Abstracts of Reviews of Effects (DARE)	Contains comprehensive reviews by the Cochrane Review Groups and abstracts of reviews by others that have been quality assessed	Many surgical topics reviewed
PubMed's Clinical Queries	PubMed filter designed by Brian Haynes from McMaster University to assist in finding the highest-quality information when searching Medline	Can be used for any topic
Australian Safety and Efficacy Register of New Interventional Procedures—Surgical (ASERNIP-S)	Systematic reviews of many surgical procedures and their outcomes New and Emerging Techniques—Surgical (NET-S) provides reviews of new surgical technologies prior to introduction into practice	Only surgical topics
CAGS/ACS Evidence-Based Reviews in Surgery (EBRS)	An online journal club format that reviews 12 current surgical publications a year that illustrate important methodological issues An archive is available with 10 years of studies with abstracts discussing clinical and methodological issues	Only surgical topics
McMaster University's Surgical Outcomes Research Centre (SOURCES)	A series of 13 articles focused on the methodology required to critically appraise the surgical literature Modeled on the "Users' Guides to the Medical Literature" published in <i>JAMA</i>	Methodology with surgical relevance
<i>BMJ's Clinical Evidence</i>	Comprehensive EBM tool Publishes and updates systematic reviews, identifies and rates recent primary literature, and provides links to relevant guidelines.	Some surgical topics
<i>ACP Journal Club</i>	Selects both primary studies and reviews from 100 clinical journals and presents them as structured abstracts with commentaries and key references Aimed at advances in internal medicine.	Includes some surgical journals
BestBETS	Provides brief reviews of the best evidence on topics specific to primarily emergency medicine From the Manchester Royal Infirmary	Some surgical topics in emergency medicine
Turning Research Into Practice (TRIP) Database	A search engine that allows simultaneous searching of multiple EBM sites to help clinicians answer common clinical questions Located in South Wales, UK	Some surgical topics
AHRQ's Effective HealthCare Program	Focuses on comparative effectiveness reviews authored by their evidence-based practices	Limited surgical topics

enough to consider an RCT unnecessary. An important caveat is that it is possible to accurately determine the effect of treatment without RCTs only in disease states that are stable or progressive. Those disease states known to be fluctuating or intermittent are prone to errors unless RCTs are used because there may be as much noise as signal.

Rare or Distant Outcomes

When either the disease or outcome of interest is sufficiently infrequent that an RCT would never be expected to accrue enough patients to decipher a difference, RCTs are logistically impossible.⁵³ Instead, the use of comprehensive registries with methodical prospective documentation of therapeutic interventions and outcomes is the only realistic way to study these rare events. A similar consideration is if the outcome of interest will occur far enough in the future that follow-up will be impractical. This would occur, for example, if one were trying to determine which of two methods of pediatric hernia repair would lead to the lowest incidence of adult hernias; a gap would be expected to be separated by more

than 40 years. Again, registries and cohort studies are much better suited to the study of these outcomes.

No Alternative Treatments

If the natural history of a given disease is known and stable or progressive and no other treatments exist, a new treatment would clearly not need to be studied in a randomized fashion. If the disease course is fluctuating by nature, it would be necessary to study the new treatment compared with placebo unless the effect were dramatic.⁵³

FAILURE TO RECOGNIZE THE IMPACT OF LIMITED GENERALIZABILITY

Because RCTs frequently include only a highly selected group of participants relative to the whole population affected with the condition under study, there have been significant concerns of the generalizability of their results. Many have argued that the results from a given trial do not directly translate to the treatment decisions of the majority of patients in "real-world" situations.⁵⁴ It has been noted in several fields

that there is a significant discrepancy between clinical trial results and clinical practice decisions.⁵⁵ Part of this is, no doubt, related to the fact that the results must be disseminated. In addition, it has been noted that most clinicians require an accumulation of supportive evidence before they will change practice patterns, not simply the result of a single RCT.

DISMISSING OF OTHER FORMS OF EVIDENCE AS INVALID

Use of the Bradford Hill Criteria of Causation

Given that the accumulation of evidence is necessary to convince most clinicians to change practice, EBM cannot afford to dismiss evidence that does not come from an RCT. A thoughtful analysis of how different types of evidence can support a given causal hypothesis is therefore necessary. This type of analysis has built on the principles that Sir Austin Bradford Hill eloquently described in his presidential address in 1965.⁵⁶ In that address, he described the nine aspects of an association that should be considered before concluding causation existed. These so-called “Bradford Hill criteria” have been revisited and serve as a useful means by which the need for the incorporation of non-RCT data can be best understood.

Incorporation of Mechanistic and Parallel Data

One author has proposed thinking of evidence as coming in the forms of direct evidence and indirect evidence that is either mechanistic or parallel.⁵⁷ Direct evidence evaluates the strength of the association, rules out the influence of plausible confounders, and evaluates the possibility of a so-called biologic gradient (called the dose-response curve). Although direct evidence is necessary to support causation, it is not sufficient because it does not explain how the intervention caused the outcome. Rather, mechanistic evidence provides support for the causal process that links that treatment to the observed effect. Key components of mechanistic evidence are the description of a plausible mechanism and coherence of that mechanism with previously accepted knowledge. Parallel evidence refers to the consideration of the replicability of the findings.

If the field of EBM is conceived too narrowly, some important types of evidence will be excluded unnecessarily. Rather, it would benefit EBM if these other types of more indirect data were incorporated with more direct lines of evidence as they certainly serve to complement and extend the type of evidence generated from RCTs.

LIMITED EMPHASIS ON THE INDIVIDUAL

Patient Preferences

Perhaps the biggest objection to the idea of EBM stemmed from the concern that medicine would become “cookbook”

in nature. The fear on the part of clinicians has been that the results of RCTs would be applied to their patients without consideration of the circumstances of the specific patient. The concern for the potential for deemphasis of the needs of specific patients is well articulated in an opinion piece by a breast cancer survivor entitled “‘Evidence of Me’ in Evidence Based Medicine?”⁵⁸ This piece highlights the limitations of the use of data from RCTs, perhaps most poignantly by pointing out that the evidence on which guidelines for chemotherapy in breast cancer have been developed does not include a consideration of the effect of the varying treatments on fertility. Because these types of issues are of critical importance to patients, there are clear limitations on the application of data from RCTs to premenopausal women whose personal preferences for fertility might alter the treatment option recommended.

Clinical Expertise

Not only are patients wary of losing their autonomy in their health care decisions, but physicians have been equally concerned about negating the value of clinical expertise.⁵⁹ In fact, clinical expertise allows the correct diagnosis to be made so that the results of EBM can be properly applied. Further, physician insight can frequently lead to an appreciation that a given patient is likely not to tolerate a particular therapy, is likely to be noncompliant, or may be more likely to suffer adverse affects.

IRONY OF EXPERT OPINION

Perhaps one of the most pointed criticisms of EBM is that its fundamental tenets are not, in fact, evidence based.⁸ Several astute authors have pointed out the obvious hypocrisy among some groups in EBM regarding the utility of expert opinion.⁶⁰ On the one hand, proponents of EBM have insisted that the individual clinician should not rely on expert opinion and have even placed this at the bottom of the evidence hierarchy. Instead, it is suggested that the individual clinician search the literature and learn how to properly evaluate, process, and summate information on a given clinical question. The proponents of EBM rightly acknowledge that this type of searching is too time consuming for the busy clinician and therefore encourage reliance on “preprocessed” sources of information, such as guidelines and reviews authored by experts. The reader can clearly see the irony in simply substituting one type of expert opinion for another. This type of hypocrisy could be more easily accepted if high-quality trials had demonstrated that employing recommendations that come from these sources results in better patient outcomes. Until this is accomplished, EBM may have to live with the criticism that it is not evidence based.

9 PHARMACOLOGIC CONSIDERATIONS IN THE ELDERLY SURGICAL PATIENT

Linda Sohn, MD, MPH, Joe C. Hong, MD, and Michael W. Yeh, MD, FACS

In 2000, the population of Americans aged 65 or greater was estimated to be 35 million, roughly 10% of the total population.¹ The latest census figures project a doubling of the elderly population by 2030, after which the proportion of elderly Americans will stabilize at approximately 20%. The aging of the US population is expected to cause a 31% increase in the general surgery workload by 2020.²

Elderly patients are not a homogeneous group; functionally, they can range from quite healthy and active to frail. However, because age-related changes occur in each organ system in all elderly individuals, this population merits special consideration when undergoing surgical procedures. In this chapter, we examine common medication and dosing issues relevant to elderly patients during the perioperative period.

The most rapidly growing segment of the elderly population corresponds to persons aged 85 and over. Thus, perioperative management must take into account the high probability that older adults will have multiple chronic medical problems such as diabetes, coronary artery disease, and chronic kidney disease. The presence of multiple medical problems is a complex medication management challenge. Medication dose adjustment and an increased frequency of medication-related adverse events are inevitable in the elderly. That said, precautions can and should be taken to reduce medication-associated risks in this population.

The medication issues most relevant to older adults include prescription of inappropriate medications, inappropriate dosing of medications, adverse drug events, drug-to-drug interactions, and polypharmacy. Polypharmacy has been identified as a medication safety issue in Healthy People 2000, a report issued by the US Department of Health and Human Services.³ Age-related changes occur in the realm of pharmacokinetics (relation between drug dose and plasma concentration) as a result of alterations in absorption, distribution, metabolism, and excretion of medications. Changes also occur at the pharmacodynamic level (relationship between plasma concentration and clinical effect), arising from altered interactions between medications and their receptors. Age-related changes affect the number of receptors, binding affinity of medications, and the resultant biologic impact of medications on the organism.

Pharmacologic Impact of Physiologic Changes Associated with Aging

Compared with young patients, elderly patients tend to have less muscle mass, more adipose tissue, and decreased total body water.⁴ These changes cause hydrophilic drugs to

have a smaller volume of distribution and a higher plasma concentration in the elderly, leading to greater pharmacologic effect for a given dose. Conversely, hydrophobic drugs will have a smaller plasma concentration but a larger volume of distribution, leading to slower clearance for a given dose.⁵

In general, organ function is inversely proportional to age. Two organ systems intimately connected to pharmacokinetics are the renal and hepatic systems. Contributors to glomerulosclerosis include normal aging as well as age-associated comorbidities such as chronic hypertension and diabetes. These changes are particularly prominent in the renal cortex, where the glomeruli become replaced by fat and fibrotic tissue over time.⁶ In addition, renal blood flow decreases with age, in parallel with a decrease in cardiac output. As a result of a reduction in glomerular capillary plasma flow rate and a depressed capillary ultrafiltration coefficient, the aging kidney has a marked reduction in glomerular filtration rate.⁷ Therefore, the rate of elimination for drugs primarily cleared by the kidneys is decreased in elderly patients. Delayed drug elimination can lead to prolonged sedative effects of anesthetic and narcotic medications. In addition, reduced renal function renders elderly patients more vulnerable to acute renal dysfunction caused by nonsteroidal antiinflammatory drugs (NSAIDs), diuretics, and aminoglycoside antibiotics.⁶

Hepatic metabolism is also compromised by aging. This arises from both reduced parenchymal hepatic mass and a 40% decrease in hepatic blood flow between the ages of 25 and 65. The synthetic function of the liver also decreases with age. A reduction in the serum albumin concentration leads to an increase in the unbound or pharmacologically active fraction of a given dose of medication.⁸ When combined, these effects are synergistic and markedly increase the potency of a given medication dose in the elderly.

Initial Medication Assessment

Older adults are the biggest consumers of medications, being responsible for 30% of prescription drug purchases and 40% of nonprescription drug purchases nationally.⁹ As such, an essential component of preoperative assessment is a complete review of all medications that the patient is taking. This includes not only prescription drugs but also nonprescribed medications such as over-the-counter medications, supplements, vitamins, and herbal preparations. The most common drugs taken by elderly Americans are shown in Table 1.

Approximately 80% of community-dwelling older adults routinely take at least one prescription medication, and 30% take at least five prescription medications concurrently.¹⁰ As

Table 1 Top 20 Prescription and Nonprescription Drugs Used by Adults Aged 57 to 85 Years in the United States¹⁰

Medication	Available OTC	Weighted Prevalence (%)
Aspirin	Yes	28
Hydrochlorothiazide	No	16
Atorvastatin	No	13
Levothyroxine	No	12
Lisinopril	No	12

Clopidogrel	No	4
Albuterol	No	4
Conjugated estrogens	No	4

OTC = over the counter.

many as one in 25 older adults is potentially at risk for a major drug-drug interaction. Thus, polypharmacy is a reality and concern for all medical professionals caring for the elderly. The definition of polypharmacy is varied. Some definitions are based solely on the number of medications; the Health Care Financing Administration (HCFA), for example, defines polypharmacy as taking nine or more medications. Other definitions take medication appropriateness into account. Not all polypharmacy can be avoided, especially given that multidrug regimens are the standard of care in the management of common chronic diseases such as diabetes, congestive heart failure, coronary artery disease, and chronic obstructive pulmonary disease. The risk of adverse events increases with age and polypharmacy, with the risk being as high as 82% in elderly persons taking seven or more medications.⁹

Certain specific classes of prescription medications merit particular attention during the perioperative period. The first class is composed of drugs exhibiting additive adverse effects [see Table 2]. Given that almost all surgical patients are administered sedatives, anesthetics, or other central nervous system (CNS) depressants perioperatively, one must account for the potential additive effect these agents may have when combined with other CNS depressants commonly taken by elderly patients on a routine basis. A theme we will revisit throughout this chapter is the fact that anticholinergic medications are strongly associated with cognitive impairment in normal elderly individuals,¹¹ as well as those with existing

Table 2 Drugs with Additive Adverse Effects

CNS depressants

Macrolide antibiotics
Quinolone antibiotics

CNS = central nervous system.

chronic neurologic conditions such as Alzheimer disease and Parkinson disease.^{12,13} Therefore, the surgical team is responsible for both taking note of anticholinergic medications routinely taken by the patient and avoiding the addition of more such medications perioperatively. Prolongation of the QT or corrected QT (QTc) interval is associated with the development of torsades de pointes, a potentially lethal ventricular tachyarrhythmia. Normal aging is associated with progressive mild increases in the QTc interval. Medications that prolong the QTc interval in an additive fashion are listed in Table 2. Inhaled anesthetic agents prolong the QTc interval,¹⁴ and this effect may be more pronounced in the elderly.¹⁵

A second class of medications that merits special attention both preoperatively and perioperatively constitutes those that alter the activity of the cytochrome P-450 (CYP) enzyme superfamily [see Table 3]. CYP enzymes, which catalyze the oxidation of organic substrates, play a critical role in the elimination of many medications. Thus, agents that inhibit or induce CYP activity have great potential to cause drug-drug interactions. A classic example is the inhibition of benzodiazepine metabolism by azole antifungal agents, which can result in a prolonged sedative effect. Another interaction relevant to cardiovascular surgeons is the inhibition of CYP-dependent clopidogrel activation by omeprazole.¹⁶

A large proportion of the US population uses nonprescription medications. In fact, about half of adults aged 65 and older regularly use over-the-counter medications.¹⁰ Research regarding the clinical benefit of herbal medications and supplements is limited. However, the increasing popularity of these supplements has spurred recent studies examining some of the most widely used supplements, such as chondroitin sulfate and St. John's wort, which is often taken by women for menopausal symptoms. St. John's wort can decrease absorption while increasing clearance of prescription drugs such as immunosuppressants and antiretrovirals, leading to lower plasma concentrations and efficacy.¹⁷ In addition, St. John's wort may also contribute to serotonin syndrome, a potentially life-threatening adverse drug reaction, when used in combination with other serotonergic drugs.¹⁸ The lack of information regarding potential side effects, drug interactions, and adverse drug events associated with supplements and herbal medications complicates medication review in older surgical patients.

Table 3 Drug Interactions Involving the Cytochrome P-450 Enzyme System⁶⁷

Enzyme	Potent Inhibitors	Potent Inducers	Substrates
CYP1A2	Amiodarone, cimetidine, ciprofloxacin	Carbamazepine, phenobarbital, rifampin, tobacco	Caffeine, clozapine, theophylline
CYP2C9	Amiodarone, fluconazole, fluoxetine, metronidazole, trimethoprim-sulfamethoxazole	Carbamazepine, phenobarbital, phenytoin, rifampin	Carvedilol, celecoxib, glipizide, ibuprofen, irbesartan, losartan
CYP2C19	Fluvoxamine, isoniazid	Carbamazepine, phenytoin, rifampin	Omeprazole, phenobarbital, phenytoin
CYP2D6	Amiodarone, cimetidine, diphenhydramine, fluoxetine, paroxetine, quinidine, terbinafine	No significant inducers	Amitriptyline, carvedilol, codeine, donepezil, haloperidol, metoprolol, paroxetine, risperidone, tramadol
CYP3A4 and CYP3A5	Clarithromycin, erythromycin, diltiazem, itraconazole, ketoconazole	Carbamazepine, <i>Hypericum perforatum</i> (St. John's wort), phenobarbital, phenytoin, rifampin	Alprazolam, amlodipine, atorvastatin, diazepam, estradiol, simvastatin, sildenafil, verapamil, zolpidem

Medication Reconciliation

Medication reconciliation is a formal process of identifying the most complete and accurate list of medications a patient is taking and using that list to provide correct pharmacotherapy for the patient anywhere within a health care system. The goal of medication reconciliation, put simply, is to eliminate unexplained differences among documented medication regimens across the continuum of care. Such discrepancies are, unfortunately, very common, occurring in up to two thirds of inpatients.¹⁹ The elderly surgical patient is particularly vulnerable as both age (odds ratio 1.16 per 5-year increase in age) and admission to a surgical service (odds ratio 3.31) have been identified as independent risk factors for medication discrepancies.²⁰ Unexplained differences in admission medications most commonly involve cardiovascular drugs.

The perioperative period represents a transition from one level of care to another, usually from an outpatient to an inpatient setting or, in a significant fraction of elderly adults, from a long-term care facility to an inpatient setting. Often certain outpatient medications, most notably anticoagulants or antiplatelet agents, are deliberately discontinued in preparation for surgery and must be thoughtfully reinstated postoperatively. New medications, such as analgesics and antibiotics, may be initiated. Opportunities for medication reconciliation and, thus, the avoidance of preventable medication errors include admission to the acute care setting and transfer or discharge to a lower level of care. We have already discussed the importance of preoperative medication assessment. At discharge, verification of the indication or pertinent diagnosis for each medication and duration of treatment, when applicable, is also essential. For example, in the event that a surgical patient develops a perioperative infection, the indication and duration of treatment of the antibiotic should be clearly labeled on the medication at the time of discharge. In this way, the complexity of medication management may be reduced for the other health care providers as well as patients and their families during the period of recovery.

Guidelines for Medication Use in the Elderly

Although a large number of medications are prescribed for the elderly, few guidelines exist for appropriate medication use in this population. Most clinical guidelines regarding

medication use arise from studies of young, generally healthy adults. Elderly individuals, particularly those older than 80 and medically complex frail elderly patients, are underrepresented in clinical drug trials; thus, the primary literature on best medication practices in this group is limited.

The Beers criteria were first introduced in 1991 as a screening tool to be used in nursing home patients and consisted of specific drugs or drug classes that should be avoided in the elderly.²¹ In 2003, the Beers criteria were updated to reflect modern medication use patterns [see Table 4] and to describe specific drug-disease combinations that should be avoided in the elderly.²² Common medication-related pitfalls in elderly surgical patients include the following:

- *Administration of diphenhydramine (Benadryl) for insomnia.* The anticholinergic effect greatly increases the risk of delirium in hospitalized elderly patients.²³
- *Administration of long-acting benzodiazepines (chlordiazepoxide, diazepam) for agitation.* These agents may cause prolonged sedation lasting for days. It is preferable to substitute short-acting benzodiazepines (lorazepam, oxazepam) at low dosages in the elderly.
- *Administration of meperidine for postoperative pain.* Meperidine is associated with delirium, hallucinations, and inadequate pain relief. Accumulation of its metabolite, normeperidine, may lead to convulsions.²⁴
- *Administration of metoclopramide (Reglan) as an antiemetic in patients with Parkinson disease.* Antidopaminergic effects may exacerbate symptoms of Parkinson disease.
- *Administration of calcium channel blockers, anticholinergics, and tricyclic antidepressants in patients with constipation.* These agents may exacerbate constipation.

Specific patient characteristics associated with increased risk of medication-related adverse events include six or more medical diagnoses, receipt of more than 11 total doses of medications per day, receipt of more than nine different medications, a history of prior adverse drug events, patients with a low body mass index, age greater than 85 years, and creatinine clearance less than 50 mL/min. Many, if not all, of these characteristics could pertain to the older patient undergoing elective or emergent surgery.

The Assessing Care of Vulnerable Elders or (ACOVE) project was launched in 2001 to develop a comprehensive set of quality assessment tools for community-dwelling persons

Table 4 Updated (2002) Beers Criteria for Potentially Inappropriate Medication Use in Older Adults²²

Drug	Category	Concern
Pentazocine (Talwin)	Opioid	More adverse CNS effects than other narcotic drugs
Meperidine (Demerol)	Opioid	Ineffective orally; may cause confusion; better alternatives exist
Naproxen (Naprosyn, Aleve), oxaprozin (Daypro), piroxicam (Feldene)	NSAID	Longer half-life; non-COX selective; long-term use at full dosages may produce GI bleeding, renal failure, hypertension, and heart failure
Indomethacin (Indocin)	NSAID	Produces the most CNS adverse effects among NSAIDs
Ketorolac (Toradol)	NSAID	May cause GI bleeding as many elderly patients have asymptomatic GI pathologic conditions
All barbiturates (unless used to control seizures)	Sedative/hypnotic	Highly addictive; cause more adverse effects than other sedative/hypnotic drugs in elderly patients
Flurazepam (Dalmane), chlordiazepoxide (Librium), diazepam (Valium)	Benzodiazepine	Very long half-life in elderly patients (often several days), producing prolonged sedation and increased risk of falls
Trimethobenzamide (Tigan)	Antiemetic	Limited effectiveness, extrapyramidal adverse effects
Amitriptyline (Elavil)	Antidepressant	Strong anticholinergic effect, sedation
Doxepin (Sinequan)	Antidepressant	Strong anticholinergic effect, sedation
Methocarbamol (Robaxin), carisoprodol (Soma), cyclobenzaprine (Flexeril), oxybutinin (Ditropan), orphenadrine (Norflex)	Muscle relaxants and antispasmodics	Anticholinergic effects, sedation, weakness; limited effectiveness in elderly patients
Chlorpheniramine (Chlor-Trimeton), diphenhydramine (Benadryl), hydroxyzine (Vistaril and Atarax), promethazine (Phenergan)	Antihistamines	Strong anticholinergic effects; nonanticholinergic antihistamines (loratadine, cetirizine) are preferred in treated elderly patients with allergic reactions
Doxazosin (Cardura)	Antihypertensive	Potential for hypotension, dry mouth, and urinary problems
Short-acting nifedipine (Procardia and Adalat)	Antihypertensive	Potential for hypotension and constipation
Clonidine (Catapres)	Antihypertensive	Potential for orthostatic hypotension and CNS adverse effects
Disopyramide (Norpace)	Antiarrhythmic	Potent negative inotrope; may induce heart failure in elderly patients; strong anticholinergic effect
Ticlopidine (Ticlid)	Antiplatelet	More toxic and less effective than aspirin; safer alternatives exist
Dicyclomine (Bentyl), propantheline (Pro-Banthine), belladonna alkaloids (Donnatal)	GI antispasmodic drugs	Limited effectiveness; strong anticholinergic effects
Chlorpropamide (Diabinese)	Antidiabetic	Long half-life; risk of prolonged hypoglycemia in elderly patients; may cause SIADH
Bisacodyl (Dulcolax)	Laxative	Long-term use may exacerbate bowel dysfunction
Cimetidine (Tagamet)	Histamine-2 blocker	CNS adverse effects, including confusion
Desiccated thyroid	Hormone	Concerns about cardiac effects; safer alternatives available.
Nitrofurantoin (Macrochantin)	Antibiotic	Potential for renal impairment; safer alternatives available

CNS = central nervous system; COX = cyclooxygenase; GI = gastrointestinal; NSAID = nonsteroidal antiinflammatory drug; SIADH = syndrome of inappropriate antidiuretic hormone.

65 years and older who are at high risk for death or functional decline.²⁵ The quality indicator domains, developed through literature review and expert panel consideration, range broadly across topics such as fall prevention, management of diabetes mellitus, and end-of-life care. A specific domain concerns appropriate medication use in the elderly.²⁶ These indicators focus on clearly identifying indications for medications, avoiding inappropriate medications according to the Beers criteria, patient or care provider education, documentation of medications, and drug monitoring after prescribing. In view of the increased demand for surgical services in the older

population, McGory and colleagues from UCLA have specifically developed quality indicators for elderly patients undergoing abdominal operations.^{27,28} Quality indicators pertaining to medication use in elderly surgical patients are listed in Table 5.

Perioperative Medications and Cognitive Dysfunction in the Elderly

From the perspective of the patient and the patient's family, one of the most important perioperative concerns in the care

Table 5 Quality Indicators for Pharmacologic Care in Elderly Patients^{26,28}

Preoperative Medication Management
IF an elderly patient is undergoing a major abdominal operation and is taking one of the following classes of medications, THEN specific instructions regarding preoperative management of the following classes of medications should be given to the patient: a. Anticoagulation medications b. Diabetes medications c. Cardiovascular medications d. Hormonal medications e. Herbal medications f. Over-the-counter medications
Perioperative Beta Blockade
IF an elderly patient is undergoing a major abdominal operation and meets the criteria for perioperative beta blockade, THEN, unless contraindicated, beta-blocker therapy should be initiated prior to operation.
IF an elderly patient undergoes a major abdominal operation and meets the criteria for perioperative beta-blockade, THEN, unless contraindicated, beta-blocker therapy should be continued postoperatively at least until discharge from the hospital.
Bowel Preparation
IF an elderly patient is undergoing a major abdominal operation and requires a mechanical bowel preparation, THEN the patient should be offered admission for the mechanical bowel preparation if he has any of the following and has no support at home: a. Impaired functional status with dependence in one or more activities of daily living b. Impaired cognition c. Inability to ambulate d. History of previously failed bowel preparation
Prophylaxis for Endocarditis
IF an elderly patient is undergoing a major abdominal operation and has valvular or congenital heart disease, an intracardiac valvular prosthesis, hypertrophic cardiomyopathy, mitral valve prolapse with regurgitation, or a previous episode of endocarditis, THEN endocarditis prophylaxis should be given.
Prophylaxis for Venous Thromboembolism
IF an elderly patient undergoes a major abdominal operation and does not have cancer or previous venous thromboembolism, THEN preoperative and postoperative deep vein thrombosis prophylaxis should be provided with low-dose unfractionated heparin or low-molecular-weight heparin.
IF an elderly patient undergoes a major abdominal operation and has cancer or previous venous thromboembolism, THEN preoperative and postoperative deep vein thrombosis prophylaxis should be provided with low-dose unfractionated heparin or low-molecular-weight heparin, in addition to mechanical prophylaxis (intermittent pneumatic compression or graduated compression stockings, or both).
Drug Indication
IF an elderly patient is prescribed a new drug perioperatively, THEN the prescribed drug should have a clearly defined indication documented in the record BECAUSE the medication may have been prescribed for an indication that was unclear or transient.

Table 5 Continued

Medication Reconciliation and Patient Education
IF an elderly patient undergoes a major abdominal operation, THEN the inpatient medical record should contain the most recent outpatient medications with dosages.
IF an elderly patient undergoes a major abdominal operation, THEN the patient or caretaker should receive the following: a. A complete list of all medications and dosages to continue on discharge from the hospital. b. A discussion with the patient or caretaker about the purpose of the drug, how to take it, and the expected side effects or important adverse reactions for all medications prescribed for outpatient use.
Avoiding Inappropriate Medications
IF an elderly patient undergoes a major abdominal operation, THEN the patient should not be prescribed any potentially inappropriate medications according to the Beers criteria, unless documented why the medication is appropriate.

of the elderly is the goal of returning to independent living. Postoperative delirium and postoperative cognitive dysfunction have both been found to predict increased morbidity and poor functional recovery after surgery,^{29,30} highlighting the central role of thoughtful perioperative medication management in older patients.

Postoperative delirium (POD) is defined as a transient confusional state with alterations in attention and consciousness.³¹ In contrast, postoperative cognitive dysfunction (POCD) is a more persistent problem defined by changes in cognitive performance. The *Diagnostic and Statistical Manual of Mental Disorder*, fourth edition (DSM-IV), recognizes POCD as a neurocognitive disorder with symptoms including difficulty staying focused on tasks and declines in learning, memory verbal abilities, perception, attention executive functions, and abstract thinking. The diagnosis of POCD requires preoperative neuropsychological testing to establish a baseline and postoperative testing to delineate the decline in cognitive function. Elderly patients are more susceptible to developing both POD and POCD.^{32,33} After noncardiac surgery, the incidence of POD ranges from 10 to 60%, whereas that of POCD ranges from 7 to 26%.^{34,35} These figures are higher after cardiac surgery, where the incidence of POD ranges from 25 to 80%, whereas that of POCD ranges from 3 to 47%.³⁶ Because POD and POCD occur so commonly in the elderly, the cumulative societal costs attributable to these potentially avoidable conditions are significant. POD has been linked to higher mortality rates, increased length of hospitalization, and increased costs of care.³⁷

The etiology of POD and POCD is still not well understood. However, there is consensus that medications, patient comorbidities, and the type of surgery all play an important role in their incidence.³⁸ Among elderly surgical patients, perioperative use of opioid analgesics, sedative-hypnotics, antihistamines, and anticholinergics is associated with POD and POCD. The specific drugs that should be avoided have been discussed above. Other contributing factors include increasing age, preoperative cognitive impairment or prior history of delirium, anemia, pain, respiratory complications, admission to the intensive care unit, infection, metabolic

derangements, and intraoperative hemodynamic fluctuations.^{30,32} Interestingly, a systematic review of anesthetic techniques did not demonstrate a benefit from neuraxial anesthesia when compared with general anesthesia in decreasing the incidence of postoperative cognitive dysfunction.³⁹

Perioperative medications play an important role in both the causation and possible prevention of POD and POCD. Although consideration to avoiding medications associated with delirium and cognitive dysfunction should, no doubt, be taken, it is difficult, if not impossible, to entirely avoid certain classes of medications, such as opioids, benzodiazepines, and other sedative-hypnotics, in the care of the elderly surgical patient. Likewise, polypharmacy and its associated risks are to some degree unavoidable in the perioperative setting. Therefore, the surgical team is best served by understanding the pharmacology of common perioperative medications in the setting of age-related physiologic changes, with the goal of making appropriate medication choices and dose adjustments to minimize drug-associated morbidity.

PHARMACOTHERAPY OF POSTOPERATIVE DELIRIUM

When strategies for avoidance of postoperative delirium have failed, pharmacotherapy may be initiated alongside other measures, such as preserving the sleep-wake cycle and maximizing cues that orient the patient to time, place, and person (it is often helpful to engage the family in orienting the patient to self in the context of familiar relationships). Systematic reviews indicate that low-dose haloperidol (< 3.0 mg/day) is equally efficacious as the atypical antipsychotics olanzapine and risperidone in the treatment of delirium. High-dose haloperidol (> 4.5 mg/day) is associated with extrapyramidal adverse effects (parkinsonism) and should be avoided. Benzodiazepines can worsen confusion and sedation in patients with non-alcohol withdrawal delirium and should also be avoided. Our preference is to initiate low-dose risperidone (0.5 mg b.i.d.) and wait 24 hours for clinical effect. Short courses lasting fewer than 5 days are generally sufficient.

Specific Drug Classes and the Elderly Surgical Patient

OPIOIDS

Opioids, such as fentanyl, meperidine, morphine, and hydromorphone, are the main mediators of analgesia and are used for nearly all patients in the perioperative setting. Their high lipid solubility accounts for their ability to rapidly cross the blood-brain barrier and bind to opioid receptors within the CNS. High lipid solubility also allows these compounds to distribute into adipose tissue. Given that the body composition of older adults is characterized by a relatively high proportion of adipose tissue, the volume of distribution for opioids is markedly increased, resulting in slower clearance.⁴ Decreased hepatic metabolism in the elderly further contributes to delayed clearance of these agents. Opioids exhibit a high degree of protein binding and are therefore affected by reduced hepatic synthetic function, particularly in malnourished patients. The increased unbound drug fraction leads to increased potency for a given dose of opioids.

Morphine exhibits a unique pharmacokinetic property not shared by the other opioids in that both the native drug

and its metabolite, morphine-6-glucuronide, have analgesic properties. Morphine-6-glucuronide is primarily eliminated by the kidney. Patients with renal insufficiency may have impaired elimination of this morphine metabolite, which may partially account for the relatively augmented analgesic effect from a given dose of morphine in the elderly population.⁴⁰ On the pharmacodynamic side of the equation, the aging brain is more sensitive to opioids irrespective of changes in drug disposition as predicted by altered physiology and pharmacokinetics.⁴¹ Dosage requirements for morphine, fentanyl, alfentanil, and remifentanyl have been shown to be roughly decreased by half.⁴²

SEDATIVES AND HYPNOTICS

Benzodiazepines, such as midazolam, diazepam, and lorazepam, are commonly administered in the perioperative period to treat anxiety and agitation. They act by enhancing the inhibitory effect of γ -aminobutyric acid (GABA) within the CNS. Like opioids, benzodiazepines are characterized by high lipid solubility, high protein binding, and predominantly hepatic metabolism. All of these factors contribute to a reduced rate of clearance in the elderly that mandates dose reduction.

Pharmacodynamic evidence also shows an increased sensitivity of older patients to benzodiazepines. Age-dependent changes in the number of GABA type A receptors have been demonstrated and may be responsible for alterations in drug sensitivity.⁴³ A 50% reduction in midazolam dosing should be considered in patients older than 70, and a 75% reduction should be considered in those older than 90.⁴²

INHALATIONAL ANESTHETIC AGENTS

Anesthetic drugs can be generally categorized as inhalational or intravenous. Contemporary inhalational drugs such as sevoflurane, desflurane, and isoflurane are delivered with an anesthesia machine via an airway conduit. Dosage in terms of partial pressure can be easily adjusted and titrated by the anesthesiologist using an agent-specific vaporizer. Inhaled anesthetic requirements are usually described in terms of the minimum alveolar concentration (MAC) that prevents movement in response to noxious stimulation. MAC declines by roughly 0.6% for each year above age 40, as shown in Figure 1,⁴⁴ a phenomenon reflecting the increased sensitivity of the aging brain to inhalational anesthetic agents. The mechanisms underlying age-related changes in sensitivity to these drugs remain unknown. However, declining neuronal bioenergetics attributable to acquired mutations in mitochondrial DNA and age-related oxidative stress were both recently shown to play a potential role.⁴⁵

Inhalational anesthetics are characterized by high lipid solubility. Recovery from inhalational anesthetics may thus be prolonged in the elderly because of their increased body fat, resulting in a higher volume of distribution. Desflurane, which is the least lipid soluble of the contemporary inhalational anesthetics, may be the agent of choice for elderly patients.

INTRAVENOUS ANESTHETIC AGENTS

Intravenous anesthetics include sodium thiopental, etomidate, and propofol. In general, they facilitate GABA-mediated inhibitory neurotransmission within the reticular

Figure 1 Minimal alveolar concentration (MAC) as a function of age. The MACs for desflurane, sevoflurane, and isoflurane decrease by about 6% per decade above the age of 40 years. The age-adjusted MAC values for this graph are based on the formula $\text{MAC fraction} = 1.32 \times 10^{-0.003 \times \text{age}}$, where MAC is the MAC fraction based on 1 MAC = MAC at age 40 years. We assume MAC at age 40 years for desflurane, sevoflurane, and isoflurane to be 6.45, 1.9, and 1.2%, respectively. Data and formula are from Eger.⁴⁴

activating system, the area of the brain principally involved in regulating arousal. Their high lipid solubility allows rapid penetration into the CNS and thereby facilitates rapid onset of action for anesthesia induction. High lipid solubility also results in a high volume of distribution over time. However, during the immediate period of anesthesia induction, only the plasma concentration of the anesthetic agent drives CNS penetration. Therefore, the initial volume of distribution is small, especially in the elderly with decreased total body water, resulting in a higher plasma concentration for a given dose. High protein binding is a characteristic of thiopental and, to a lesser extent, etomidate. In the setting of low serum albumin in the elderly, we observe the recurring theme of an increased fraction of unbound drug, resulting in increased potency for a given dose. Both thiopental and etomidate are hepatically cleared. The age-adjusted dose for both agents is therefore reduced by roughly 30 to 50%.⁴⁶

In contrast to what is observed with inhalational anesthetics, end-organ sensitivity to thiopental and etomidate does not appear to change with age, as confirmed by pharmacodynamic studies.⁴⁷ Thus, the dose required to achieve anesthesia using thiopental or etomidate is reduced solely as a function of pharmacokinetic principles.

Propofol is perhaps the most commonly used modern intravenous anesthetic for induction of general anesthesia. The high lipid solubility of propofol results in rapid onset of action. Awakening from a single bolus dose is more rapid and accompanied by less of a “hangover effect” than recovery

from thiopental or etomidate. Although these characteristics seem to make propofol more favorable in the elderly, compared with thiopental and etomidate, propofol causes more cardiovascular depression.⁵ Propofol causes a dose-related drop in blood pressure that results primarily from a decline in systemic vascular resistance. Pharmacokinetic evidence supports the need for reduced dosing of propofol in the elderly. As seen with the other intravenous anesthetic agents, propofol displays the triad of small initial volume of distribution, high protein binding, and hepatic metabolism. The half-life of propofol is prolonged in elderly individuals.⁴ For these reasons, a propofol dose reduction of 30 to 50% is prudent.⁴⁶ The clinical pharmacology of anesthetic agents in the elderly is summarized in Table 6.

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking agents are ionized, highly water-soluble compounds that have a small volume of distribution, particularly in elderly patients, who possess a reduced extracellular fluid volume.⁴⁸ A delayed onset of action for most of these drugs has been attributed to decreased cardiac output and decreased regional blood flow to skeletal muscle. The duration of neuromuscular blockade in the elderly varies according to the specific agent. Aminosteroids, such as pancuronium, vecuronium, and rocuronium, undergo organ-dependent clearance by the kidney and, to a lesser extent, the liver. The duration of these agents, as measured by their recovery indices, can be increased by as much as 200% in the elderly when compared with young adults.⁴⁹

Table 6 Clinical Pharmacology of Anesthetics and Analgesics in the Elderly

Drug	CNS Sensitivity	Pharmacokinetics	Dose Adjustment
Inhalational anesthetics	↑		↓
Thiopental	↔	↓ initial distribution volume	↓
Etomidate	↔	↓ initial distribution volume	↓
Propofol	↑	↓ initial distribution volume	↓
Midazolam	↑	↓ clearance	↓
Morphine	↑	↓ clearance	↓
Hydromorphone	↑	↓ clearance	↓
Fentanyl	↑	↓ clearance	↓

CNS = central nervous system.

In contrast, newer (and more costly) benzylisoquinolinium compounds, such as atracurium and cisatracurium, are cleared in an organ-independent fashion via Hofmann degradation and ester hydrolysis. The recovery period for these agents is therefore not significantly prolonged in the elderly. Likewise, the recovery period for succinylcholine, a depolarizing relaxant, is not different in elderly patients. No changes in the sensitivity of the neuromuscular junction to blocking agents with age have been demonstrated. Thus, the clinical differences observed with neuromuscular blocking agents in the elderly are purely ascribed to pharmacokinetic alterations.

Regional versus General Anesthesia in the Elderly Patient

In the elderly population, postoperative complications most commonly involve neurologic, pulmonary, and cardiovascular compromise. When feasible, regional anesthesia has many purported benefits over general anesthesia for the elderly. Established benefits involving the CNS include reduced stress, decreased postoperative pain, decreased opioid requirements, and the potential to reduce or avoid anesthetic agents.⁵⁰ In regard to the pulmonary system, regional anesthesia may permit avoidance of endotracheal intubation and mechanical ventilation, thus reducing respiratory complications such as pneumonia and respiratory depression.⁵¹ From a cardiovascular standpoint, the superior analgesia provided by a regional technique over intravenous or oral opioids may reduce myocardial stress, thereby decreasing the incidence of postoperative cardiac events.⁵² Despite these benefits, no survival advantage has been demonstrated for regional or epidural anesthesia when compared with general anesthesia. As mentioned above, multiple studies comparing intravenous opioid analgesia with epidural analgesia in the elderly showed no significant difference in regard to postoperative mental capacity and cognitive function.³⁸

Antibiotic Use in the Elderly Surgical Patient

Optimal perioperative antibiotic management in elderly patients is, in some respects, similar to that applicable to the general adult population. Prophylactic antibiotics should be administered within 1 hour prior to skin incision and

discontinued within 24 hours after surgery in keeping with the Surgical Care Improvement Project performance measures.⁵³ The consequences for failing to follow these guidelines appear to be more severe in the elderly. Older patients who did not receive appropriately timed preoperative antibiotics were found to have a twofold increase in the 60-day mortality rate following general or orthopedic surgery in a matched control study.⁵⁴ Timely discontinuation of prophylactic antibiotics is essential to minimizing the risk of *Clostridium difficile* colitis, a condition that is both disproportionately common and disproportionately lethal in older adults.⁵⁵

Drug-drug interactions are a concern when administering antibiotics for both prophylaxis and the treatment of established infections. Antianaerobic second-generation cephalosporins that possess an *N*-methylthiotetrazole side chain, such as cefamandole and cefotetan, can potentiate the anticoagulant effect of warfarin. Aminoglycosides and vancomycin are both associated with nephrotoxicity and ototoxicity. Nephrotoxicity can be exacerbated by coadministration of NSAIDs as well as radiographic contrast agents, whereas ototoxicity can be exacerbated by concurrent loop diuretic use.⁵⁶ Although aminoglycosides have been, to some degree, replaced by fluoroquinolones in the treatment of resistant gram-negative infections, the fluoroquinolones are not without their own dangers. Gatifloxacin, levofloxacin, and moxifloxacin prolong the QT interval and have been associated with torsades de pointes, particularly when administered in conjunction with class III antiarrhythmic drugs such as ibutilide, sotalol, and amiodarone.^{57,58}

Perioperative Management of Anticoagulation and Antiplatelet Therapy in the Elderly

A significant fraction of elderly surgical patients receive chronic warfarin anticoagulation. The most common indication for anticoagulation is atrial fibrillation, which is associated with advancing age and male sex. The prevalence of atrial fibrillation in persons aged 80 and above is approximately 10%.⁵⁹ Because anticoagulation is recommended only for patients at intermediate or high risk for ischemic stroke according to the Congestive Heart Failure, Hypertension, Age, Diabetes, Stroke (doubled) risk scoring system (CHADS₂), slightly more than half of all patients with atrial fibrillation are maintained on warfarin.⁶⁰

Warfarin should generally be stopped 5 days prior to major elective surgery. Bridging therapy with either intravenous unfractionated heparin or, more commonly, subcutaneous therapeutic dose low-molecular-weight heparin (e.g., enoxaparin 1 mg/kg b.i.d.) is recommended for patients with mechanical heart valves or atrial fibrillation with a moderate to high risk of thromboembolism.⁶¹ No bridging therapy is required in patients with a low risk of thromboembolism.

When considering the timing of resumption of anticoagulation postoperatively, it is important to remember that, in almost all cases, the risk of death or disability attributable to major hemorrhage far exceeds that attributable to thromboembolism.⁶² For this reason, it is recommended that initiation of therapeutic doses of unfractionated or low-molecular-weight heparin be delayed 24 to 72 hours after surgery or until that time at which hemostasis is secured. Warfarin, because of its delayed onset of action, can generally be resumed 12 to 24 hours after surgery.⁶¹

In contrast to warfarin, which is a vitamin K antagonist, the novel orally bioavailable anticoagulants dabigatran, rivaroxaban, and apixaban act by directly inhibiting thrombin (dabigatran) or factor Xa (rivaroxaban, apixaban). They carry the advantages of rapid onset of action and predictable anticoagulant effect, such that monitoring of the international normalized ratio is not necessary. These agents may achieve Food and Drug Administration approval soon after the

publication of this chapter. The elderly have already been identified as an at-risk population for adverse drug events involving novel oral anticoagulants, which all undergo metabolism by CYP enzymes prior to renal elimination.⁶³ They also interact with aspirin as well as NSAIDs, which are frequently prescribed for arthritis relief in the elderly.

The majority of coronary stents being placed during modern percutaneous coronary interventions are drug-eluting stents.⁶⁴ As stent thrombosis is associated with high rates of myocardial infarction and death,⁶⁵ it is currently recommended that patients receiving drug-eluting stents receive an uninterrupted 12-month course of dual-antiplatelet therapy with aspirin and clopidogrel. For bare metal stents, a minimum of 6 weeks is recommended.⁶¹ Elective noncardiac surgery should be postponed beyond this time period whenever possible.

VENOUS THROMBOEMBOLISM PROPHYLAXIS

The risk of thromboembolism increases with age. In elderly patients at moderate or high risk for perioperative venous thromboembolism, pharmacologic prophylaxis with low-dose unfractionated heparin or low-molecular-weight heparin should be considered. Age-associated reductions in renal function can impair the clearance of low-molecular-weight heparins.⁶⁶

10 ADVANCE DIRECTIVES, DO NOT RESUSCITATE ORDERS, AND POWER OF ATTORNEY FOR HEALTH CARE

Margaret L. Schwarze, MD, MPP, FACS

In 1975, Karen Ann Quinlan suffered an anoxic brain injury that left her neurologically devastated.¹ Her parents, devout Catholics, fought her physicians (who insisted on continuation of life-supporting therapy because she did not meet the criteria for brain death) all the way to the New Jersey Supreme Court. Julia and Joseph Quinlan requested discontinuation of life-supporting therapy, believing that Karen would not have wanted to continue life without cognitive function attached to a ventilator. In 1976, the court decided in favor of Karen's parents; however, when Karen's physicians discontinued the ventilator, she continued to live without its support. Although she died 9 years later in a nursing home from fulminant sepsis associated with her persistent vegetative state, her case started a national discussion about end-of-life care, withdrawal of life-supporting therapy, and protection of patient preferences in the setting of incapacity.

As they watched the Quinlan case unfold, many Americans became concerned about their own ability to protect personal preferences for end-of-life therapies in the setting of a future event that would render them unable to state their choices. In the 1970s, respect for patient autonomy had emerged as the dominant concept for the ethical care of patients. The Quinlan case raised concern that patients' autonomy may no longer be respected once they lost the capacity to state their choices, particularly choices about long-term, invasive therapies such as ventilatory support or dialysis. Although Karen Ann Quinlan's clinical course did not evolve in line with expectations, the legacy of her ordeal is the resulting national interest in documenting future wishes for life-supporting therapy in the event that a person can no longer speak for himself or herself.

Advance Directives and Living Wills

An advance directive is a legally binding document designed to express patients' treatment preferences when they are no longer able to do so themselves. Typically, the advance directive assumes the form of a living will whereby the "will" is carried out while the patient is still alive but is unable to make treatment decisions. Other forms of advance directives include but are not limited to a directive to forego cardiopulmonary resuscitation (CPR) in the event of cardiac arrest (do not resuscitate [DNR]) and designation of a health care decision maker (durable power of attorney [POA] for health care).

LIVING WILL

In its most simple form, the living will is a set of conditional instructions formally documented by a patient to enumerate his or her wishes in the setting of future incapacity. The primary aim of the directive is to protect patient autonomy: the patient's right to choose or refuse therapy at any given time. Although a majority of advance directives express wishes for limitation of life-supporting therapy, it should not be assumed that all advance directives state a preference for withdrawal of life-supporting therapies as some patients may prefer aggressive therapies in nearly all clinical situations.

The living will is structured in language designed to ensure that the patient's treatment preferences are honored [see *Figure 1*]. For example, many directives will provide a conditional statement such as "In the event that I develop a terminal illness . . ." or "In the case that I suffer permanent brain injury such that I no longer have cognitive functioning . . ." These hypothetical states are then followed by a list of the patient's preferences for continuation or withdrawal of life-supporting therapies. For example, "The following therapies should be continued: tube feedings and intravenous hydration" and "The following therapies should be discontinued: ventilator support, hemodialysis, and blood transfusions." Unfortunately, in practice, these hypothetical clinical states tend to be dominated by vague and nonspecific language that typically requires significant interpretation and abstraction of the patient's desires.²

Most advance directives are created with the assistance of the patient's primary care physician, nurse practitioner, social worker, lawyer, or clergy member. Nearly all hospitals receiving federal funding have access to resources to support their patients' creation of an advance directive [see Patient Self-Determination Act of 1990, *below*]. In addition, there are state-sponsored Web sites and government offices to assist patients in formulating their own advance directive (see <http://www.nationalhealthcaredecisionsday.org/resources.htm> and <http://www.caringinfo.org/stateaddownload>). Ideally, an advance directive is best created in consultation with a physician or other qualified health care provider who can both illustrate the clinical situations that patients might anticipate and discuss the advantages and disadvantages of treatment options. In this way, patients are more fully informed about their treatment choices and have greater potential to express their autonomous wishes for clinical states with which they may be unfamiliar.

9. STATEMENT OF DESIRES, SPECIAL PROVISIONS OR LIMITATIONS

This form is part of my Power of Attorney for Health Care. The following are some specific provisions for my health care agent(s) or others providing my care.

I, _____, have initialed or have had initialed for me each choice that represents my preferences for future medical care. I have drawn a line through any written instructions below that I do not want. These preferences should be considered by my physician and agent when I am incapable to make my own decisions. I have defined quality of life as meaningful interactions with my family, friends and environment.

CARDIOPULMONARY RESUSCITATION (CPR)

NOTE: My CPR preference may be reconsidered by my agent in light of my other instructions or new medical information, if I become incapable of making my own decisions. If I do not want CPR attempted, my physician should be made aware of the preference. A "No CPR" preference if indicated below will not, in itself, stop paramedics from attempting CPR in an emergency.

☐ I want Cardiopulmonary Resuscitation (CPR) attempted if my heart stops.

☒ I want CPR attempted if a successful attempt may result in the recovery of my ability to meaningfully interact with myself, my family, friends and environment. (The question of a meaningful recovery if my heart stops needs to be considered by me or my agent and physician before an emergency.) *If I have Alzheimer's, have had a severe stroke or have a terminal illness I do NOT want CPR.*

☐ I do not want CPR attempted if my heart stops.

☒ I want to be intubated and placed on a respirator if this may result in the recovery of my ability to meaningfully interact with myself, my family, friends and environment. (The question of a meaningful recovery needs to be considered by me or my agent and physician before an emergency.) *If I have Alzheimer's, have had a severe stroke or have a terminal illness I do NOT want to be intubated or on a respirator.*

☐ I do not want to be intubated or placed on a respirator.

LIFE PROLONGING TREATMENTS

☒ I reach a point when it is reasonably certain that I will not recover my ability to meaningfully interact with myself, my family, friends and environment, I want to have all treatments used to prolong my existence stopped or withheld. Treatments would include tube feedings, antibiotics, anti-arrhythmic drugs, kidney dialysis, IV's, and long term respirator.

PAIN CONTROL

☒ In the event that life-prolonging treatments are discontinued, I want medical and nursing care that will make me comfortable, even it hastens my death.

Figure 1 A living will designating conditions for resuscitation.

USE OF ADVANCE DIRECTIVES

There has been significant debate in the literature regarding the effectiveness of advance directives whereby many small investigations³⁻⁵ and one very large⁶ investigation of the use of advance directives showed minimal effectiveness of these documented preferences to limit life-supporting therapy. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) is a randomized, controlled trial that enlisted a trained nurse to facilitate and encourage communication about prognosis and preferences for end-of-life therapies (including creation of advance directives) between physicians and over 2,500 patients (in the intervention group) admitted to the intensive care unit (ICU).⁶ Despite this aggressive intervention, there was no

significant reduction in the provision of aggressive therapy at the end of life demonstrated by specific end points such as days in the ICU, number of days patients spent comatose before death, and even reported pain. This study called into question the effectiveness of advance directives and specifically raised concerns that active intervention to improve communication and elicit patient preferences could not reduce unnecessary and potentially unwanted care at the end of life. Although this study was criticized for using a potentially ineffective intervention (nurse advocate) rather than other mechanisms to change physician behavior (peer-to-peer education or key opinion leader demonstration),⁷ SUPPORT has been widely cited as evidence that advance directives are ineffective for protecting patient preferences regarding end-of-life therapy.

Recently, one robust study from the University of Michigan documented the value of advance directives.⁸ This study examined 3,746 retired citizens over a period of 6 years and found that just over 70% of patients died in the setting of physical incapacity to make personal health care decisions. For these patients, the advance directive was present 67% of the time and was in concordance with the care provided at the end of life based on retrospective interviews with family members. Although this study was unable to verify whether the care provided was truly in line with the preferences stated in the patient's directive, it is encouraging that the patients' surrogates found the advance directive informative and that, clinically, this was effective for limiting unwanted aggressive therapy at the end of life.

BARRIERS TO THE USE OF ADVANCE DIRECTIVES

Although a living will may provide important information about an incapacitated patient's preferences, there are many barriers to the effective use of written advance directives. Perhaps the most substantive barrier is that only a small proportion of the American population has a living will or advance directive. Reports vary on the percentage of Americans who actually have an advance directive, estimating that anywhere between 20 and 40% of citizens have either a living will or durable POA for health care.^{9,10} However, studies have documented that the percentage of patients who have an advance directive who are older or frail is substantially higher, on the order of 60 to 80%.^{8,11}

Other barriers to the use of advance directives exist. These barriers include a failure to understand the consequences of the decision to be made, a document that is vague or not applicable to the clinical condition at hand, inability to find the document when it is needed, and failure to update the advance directive as clinical conditions or patient preferences change over time. One additional barrier is the failure of the patient to discuss personal preferences with family members or failure to inform members of his or her decisions such that conflict arises when an unfamiliar or unprecedented choice has been documented. In this setting, family members who raise issues regarding the validity of the directive (rightly or wrongly) impede implementation of the directive as it was created.

PATIENT SELF-DETERMINATION ACT OF 1990

Increased recognition of the problem of underuse of advance directives arose in the late 1980s. Concerns grew that with improvements in technology, many elderly or terminally ill patients were receiving care they would have refused had they had an advance directive to delineate their choices. To reverse this trend, Congress enacted the Patient Self-Determination Act of 1990 (PSDA).¹² This law mandates that all health care facilities receiving federal funding (i.e., Medicare and Medicaid) inform patients that they have the right to accept or refuse care at any time. Although the law was designed to increase the use of advance directives, this mandate is distinctly limited in its scope. Hospitals are required only to inform the patient in writing that he or she has the right to have or create an advance directive, to offer information regarding the creation of such directives, and to ask patients whether they already have an advance directive.¹³ There is no requirement within the mandate to ask patients

directly whether they would like to create an advance directive at the time of the admission; the mandate requires only that the hospital provide information about the mechanics of creating an advance directive. Furthermore, there are no specifications about who should have this discussion with the patient, and as such, the PSDA is typically satisfied by answering one of many questions on the nursing intake form at the time of the patient's admission to the hospital.

Other initiatives to increase the use of advance directives have had success at the local and regional levels. One example of a successful program implemented at the state level is the Physician Orders for Life-Sustaining Treatment (POLST) project, which was started in Oregon in 1991 and implemented in 1995.¹⁴ This physician order sheet is linked physically (typically, the order set is located in the patient's place of residence) to the patient and is used to assert preferences for an array of life-supporting therapies, including CPR, tube feedings, and even antibiotics. Currently, seven states have adopted a POLST program (Washington, Oregon, California, West Virginia, California, Tennessee, and North Carolina) through either legislative mandate or regulatory oversight. Programs and program initiatives are different in each state, but the unifying dimension of each POLST program is the set of medical orders that clearly delineate issues such as "comfort measures," instructions for hospital transfer, and continuation or suspension of life-sustaining therapies frequently needed in patients with advanced progressive illness.¹⁵ A recent study demonstrated the effectiveness of this program for both documenting the care preferences of POLST participants and effecting limitations of unwanted life-supporting therapy while maintaining preferences for medical interventions for those who choose more aggressive care.¹⁶

On the local level, over 90% of the residents who die in La Crosse, Wisconsin, have an advance directive because of significant effort by local hospitals, concerned physicians, and health care providers.¹⁷ Gundersen Lutheran Hospital and its director of medical ethics, Dr. Bernard (Bud) Hammes, have spent over 15 years training social workers, nurses, physicians, and other providers to create advance directives with their patients using extensive conversations and involvement of family members to design a directive tailored more specifically to the patient's preferences than a typical living will. This initiative, called "Respecting Your Choices," overcomes the main barriers to advance directive use by creating consensus among family members, promoting the ready availability of these directives, and tailoring the proscribed treatments or limitations for therapy according to an informed patient's choice.¹⁸ The program is highly effective in establishing advance care planning for members of this community and preserving preferences for treatments at the end of life.

USE OF ADVANCE DIRECTIVES IN SURGICAL PATIENTS

To date, there is barely any information regarding how frequently surgeons use advance directives for their patients.¹⁹ Other than the literature regarding the use of DNR orders in the operating room (see below), little is known about how surgeons use advance directives or whether the presence of an advance directive influences surgical decision making. To date, the modest data available reveal a broad range of attitudes about advance directives whereby some surgeons report

routine inquiry and use of advance directives as an important part of their practice, whereas others see advance directives in direct conflict with the surgical plan.²⁰ Nonetheless, there is some information to suggest that surgeons value the utility of an advance directive as it can serve as a guide to patients' preferences in the postoperative setting when life-supporting therapy has become ineffective or patient survival is unlikely.²⁰

Two studies have attempted to implement increased use of advance directives for surgical patients by employing a nurse facilitator or consultant anesthesiologist to discuss advance directives during the patient's preoperative clearance visit.^{21,22} Although both studies were able to enhance the effectiveness of the relationship between the patient and the patient's health care POA, the surgeon was uniquely circumvented in both trials. As such, these interventions were unable to evaluate the effect of advance directives on surgical decision making or how patients' preferences for life-supporting therapy would be considered perioperatively.

Do Not Resuscitate Orders

A DNR order is another form of advance directive designed to protect and enhance patient autonomy. Although physicians frequently imply alternative meaning to a patient's DNR status,²³⁻²⁶ particularly inferences about the patient's goals of therapy, a DNR order indicates only that the patient does not want CPR in the event of a cardiac arrest. DNR orders are particularly desirable for patients for whom CPR is unlikely to provide an effective resuscitation. Patients who have terminal illness or are debilitated or frail may prefer to avoid the trauma and violence that accompanies the performance of chest compressions and intubation during the resuscitative efforts at the time of cardiac arrest.

There is significant confusion in practice regarding the meaning of DNR orders. This includes both making assumptions that the patient who has a DNR order does not want treatment for an acute or chronic condition²⁷ and failing to provide other components of the resuscitative effort (vasoactive agents, intubation, cardioversion) to patients who have DNR orders. In some institutions, the DNR form can read like a menu of interventions whereby patients, with their physician's help, are asked to check off therapies from a list of therapies that they do and do not want.²⁸ Remembering that DNR means simply "no CPR" can help prevent misapplication of the DNR directive during a critical moment when other lifesaving measures may be needed and would be in line with patient preferences. Patients who wish to avoid intubation, cardioversion, or injections of epinephrine should have this clearly stated in their chart and health care providers should be apprised of these choices.

Some patients with a poor long-term prognosis who would benefit from avoiding CPR during cardiac arrest do not have a DNR order.^{29,30} Sometimes this occurs because patients fear that their DNR status will translate a message about other therapies they would truly prefer, particularly aggressive therapy that may provide significant improvement in their quality of life. Also, this occurs because the patient or physician has an overly optimistic perception of the patient's prognosis or chance of survival based on assumptions about the patient's disease state. Additionally, some patients for whom

CPR is very unlikely to be successful refuse to change their resuscitation status because they are overly optimistic about the effectiveness of CPR. Although there are many possible reasons for this, the influence of the popular media cannot be overlooked. One study found that the success of CPR in television dramas was greater than 60%, whereas rates of actual in-hospital survival of cardiac arrest vary from 6 to 15%.³¹ Patients may be overly optimistic about their chances of surviving a cardiac arrest and as such are not willing to forego the opportunity to undergo what they believe to be a potentially lifesaving procedure.

DNR in the Operating Room

A decision to create a DNR order should result from a thoughtful and informative conversation between a patient, his family members or social support, and his physician. In this way, clarification of the directive to forego CPR in the event of a cardiac arrest and consideration of the patient's goals of therapy can be well delineated. A patient who chooses to forego CPR would not necessarily also choose to forego aggressive interventions to improve or prolong his or her life. As such, patients who have active DNR orders may desire and present for surgical therapy.³² This has led to a significant conundrum for surgeons and anesthesiologists who provide care for these patients.

In the operating room, patients frequently require intubation or vasoactive medications based on their anesthetic requirements. Furthermore, surgical therapy (apart from the anesthetic) has the potential to cause cardiac arrest depending on the patient's comorbidities or the type of surgery required (e.g., cardiac surgery). As such, surgeons and anesthesiologists alike have historically assumed that DNR orders should be suspended intraoperatively.³³ This stance may seem justified given that cardiac arrest in the operating room is frequently iatrogenic or potentially treatable and is certainly distinct from cardiac arrest that occurs outside the operating room. Nonetheless, assuming that all DNR orders should be suspended during an operation completely violates the patient's right to make an autonomous decision about his or her health care.

Although it may be perfectly appropriate to suspend a DNR order intraoperatively, this should be done only after the surgeon has a detailed discussion with the patient, his or her family, and the anesthesiologist.³⁴ The desire for a surgical procedure to improve quality of life while foregoing the additional trauma of CPR intraoperatively is not necessarily inconsistent with therapeutic goals and should be respected by both surgeons and anesthesiologists. The American Society of Anesthesiologists and the American College of Surgeons support patient autonomy in this setting and have codified this in their guidelines to physicians.^{35,36} The recommendation from both societies is to "review and reconsider" the order not to perform CPR prior to a surgical procedure. After involving the patient in the decision-making process in consultation with the anesthesiologist, a decision can be made to either suspend or continue the patient's DNR order intraoperatively.³⁷ The not uncommon practice of routinely suspending a patient's DNR order without first discussing this with the patient or by refusing to operate on a patient unless the DNR order is suspended should not be continued as this is a clear violation of patient autonomy.

Power of Attorney for Health Care

In conjunction with or instead of a living will, patients will frequently name a durable power of attorney for health care decision making (POA, DPOA, or, in some regions, DPHC). By appointing a dedicated surrogate decision maker, patients can avoid some of the problems of deciphering the vagaries of a specific clinical situation associated with the use of a living will. To be effective, patients should appoint a decision maker who understands their desires for medical therapy and their beliefs regarding the pursuit of life-supporting therapy. Ideally, the person appointed should be able to make decisions according to the preferences of the patient and in line with the patient's previously stated choices regarding life-supporting therapy.

DECISION-MAKING CAPACITY

When patients are unable to make decisions about their health care, surgeons should turn to the person designated as the patient's POA to obtain consent for therapy and to discuss the goals of care. It is not always obvious when patients are unable to make decisions about their health care; as such, it is important to consider the patient's capacity to make a decision, particularly when the decision the patient is making seems irrational or diametrically opposed to medical advice. It must be noted that decision-making capacity is distinct from competence. Competence is typically a legal determination made by a judge, and decision-making capacity is relegated to the physician³⁸ and is typically specific to the decision at hand, although it may apply to all medical decisions for a specific period of time.

Decision-making capacity is clearly defined as the patient's ability to decide according to his or her wishes as related to the specific medical decision at hand. To have decision-making capacity, the patient must understand the clinical choices presented, have insight into the consequences of the decision, be able to manipulate the information rationally, and be able to state his or her preferences.³⁹ (One helpful mnemonic for quickly assessing decision-making capacity in critical situations is CURVES: Choose and Communicate, Understand, Reason, Value, Emergency, and Surrogate.⁴⁰ Emergency refers to the emergency situation in which provision of care is required to prevent immediate loss of life or limb, a unique instance for which consent is implied or assumed when an appropriate surrogate decision maker cannot be found rapidly.)

By definition, patients heavily sedated in the ICU do not have decision-making capacity as they are unable to state their preferences even though they may understand the choices and consequences if they were not sedated to receive life-supporting therapy. Although determination of decision-making capacity for the unconscious patient is straightforward, there are many situations in which consultation from other health care providers is necessary to determine a patient's decision-making capacity. Although disagreement with recommended therapy is a sign that patients may not have decision-making capacity, it is important to note that simple refusal of medical therapy is not evidence of a lack of capacity. Furthermore, patients who acquiesce to medical therapy cannot be assumed to have capacity as well, although often it is more difficult to determine that they lack capacity in the setting of consent to medical care.

It is important to note that some patients who are legally competent to make decisions about other aspects of their life may have limited insight or understanding about the specific medical decision with which they are confronted. A noted example of this problem is the case of Mary Northern, a 72-year-old female who presented to a Tennessee hospital in 1978 with gangrenous feet. The patient was perfectly lucid and able to competently decide for herself regarding all other aspects of her life and care; nonetheless, she maintained a delusional belief that her feet were black from soot and dirt. The court decided in this case that the patient lacked the capacity to make a decision about amputation but did not lack the capacity to make other health care or personal decisions. Her delusion about the cause of her necrotic feet interfered with her ability to understand the critical nature of her illness. Without understanding and insight, the court declared that she did not have the decision-making capacity to refuse an amputation; however, the court affirmed her ability to decide about other aspects of her care, unrelated to treatment for her lower extremity gangrene.⁴¹

For help determining decision-making capacity, surgeons should turn to colleagues in psychiatry, neurology, social work, or psychology or obtain an ethics consultation. In turn, these consultants will assess the patient's mental functioning, cognition, and understanding and insight into the decision to be made. In some cases, it may be helpful to have more than one consultant evaluate and document the patient's capacity for decision making as the determination may be nuanced. Once it has been determined that the patient does not have the capacity to make a decision about treatment, a surrogate decision maker is required to make the decision for the patient.

ACTIVATION OF THE DURABLE POWER OF ATTORNEY

When it has been determined that a patient does not have decision-making capacity, the patient's durable POA (if the patient has named a POA) is "activated." Once the POA is activated, all medical decisions must be made by the POA unless the patient's POA is subsequently inactivated. Because of the potential to forget to inactivate the POA, in practice, it is unusual to activate a patient's POA when patients appear to be temporarily unconscious or heavily sedated in the ICU. In this setting, surrogate decision makers are still used for medical decision making; however, the formal activation of a POA does not occur. The process for activating a POA typically requires documentation in the patient's chart by more than one health care provider that the patient does not have decision-making capacity. Many states specify which health care providers have the expertise to formally determine capacity. In addition, hospitals may require completion of a specific form to activate the patient's POA. As this varies from state to state, it is helpful to refer to the policy of the hospital or institution where care is being provided to comply with specific policy. It is important to remember that the POA will need to be inactivated formally if the patient regains the capacity to make medical decisions. Failure to document resumption of capacity can interfere with the patient's right to make autonomous decisions.

SURROGATE DECISION MAKING

When patients do not have decision-making capacity, physicians are obliged to find someone who can make decisions

for the patient. If the patient has previously designated a durable POA for health care, the POA is the first person health care providers should turn to for decision making. Often the patient's POA is not the person who accompanied the patient to the hospital or may not be as emotionally close to the patient as other family members or friends. Although the POA has legal authority to make decisions for the patient, it is appropriate, if not essential, to involve other family members and close friends in the decision-making process, particularly for decisions about the withdrawal or continuation of life-supporting therapy.

A significant portion of patients will not have appointed a POA, and as such, a surrogate decision maker must be determined. In the state of Illinois, the list of potential surrogates is codified according to the following priority: the patient's guardian (if a guardian exists), spouse, adult son or daughter, parent, adult brother or sister, grandchild, close friend, or guardian of the estate.⁴² Although this is not codified quite so specifically in other states, many hospitals employ a similar priority status in their institutional policy regarding appropriate surrogates. Although this delineation is designed to give authority to those highest on the list, surgeons should recognize that those with lower status on the priority list may at times be better decision makers for the patient than an estranged spouse or family member who has had little to no recent contact with the patient. In addition, although decision making has the potential to create conflict, consensus among multiple interested parties is preferable to simply ceding authority to the surrogate decision maker highest on the list.

Once a surrogate has been designated, he or she will be asked to make medical decisions in accordance with choices the patient would have for himself or herself if he or she had the capacity to make a decision. Sometimes the patient will have previously documented or discussed his wishes for specific clinical situations with the surrogate. Often this is not the case, and the surrogate will have no direct information with which to make a decision. In this case, the surrogate will need to use his or her knowledge of the patient's values and goals to make a decision that is most likely to be in line with

the patient's preferences. This method for making a medical decision when specific choices are unknown is called "substituted judgment." If the surrogate is unfamiliar with the patient's values or is unable to use this information to make an informed decision, the surrogate should decide in accordance with what is in the patient's best interest (called the best interest standard).

Sometimes surrogates may be making decisions that seem inconsistent with the patient's best interest or contrary to the physician's impression of the patient's previously stated wishes. It is understandable that a patient's relative or friend may want to pursue aggressive therapy for his or her loved one. Often, with gentle guidance, the surrogate can be redirected to make a decision for the patient in line with the patient's preferences rather than in line with the desires of the decision maker. On rare occasions, a surrogate decision maker will decide in accordance with ulterior motives such as dependence on a social security check or other secondary gains. In this situation, the surrogate may need to be disqualified as a decision maker to establish an alternative surrogate who will honor the patient's preferences. Consultation with the ethics service or other institutional support for dispute reconciliation is recommended in such difficult cases.

Conclusion

Advance directives such as a living will, a DNR order, and a designation of a durable POA for health care are legally binding mechanisms to preserve patient autonomy when patients have lost decision-making capacity. Although these directives are frequently used to make decisions regarding life-supporting therapy, surgeons may also need to refer to these documents or to patients' surrogates for surgical decision making to treat patients in accordance with their autonomous wishes.

12 TRANSPLANT IMMUNOLOGY: BASIC IMMUNOLOGY AND CLINICAL PRACTICE

Philip Wai, MD, and David P. Foley, MD

Engraftment of a transplanted organ into an allogeneic host triggers a cascade of immunologic responses in the host that are designed to facilitate graft rejection. Modern donor-to-host matching techniques and immunosuppression protocols have successfully tempered this natural immune response, so graft survival has dramatically improved. Currently, solid-organ transplantation has become the definitive therapy for decreasing mortality in patients with end-stage organ disease. However, transplant immunosuppression remains less than ideal because of its adverse effects, some of which include increased risks of opportunistic infections and malignancy. Optimizing graft survival by precisely downregulating the host response to graft rejection while preserving host immune defenses against pathologic and infectious agents remains poorly understood and elusive in current clinical practice.

In the following discussion, we have divided the chapter into two parts. The first part focuses on the basic immunology underlying alloantigen recognition and host response to a transplanted organ. The second part discusses the clinical management of donor organ and host compatibility in the context of kidney transplantation. Topics include graft rejection, recipient desensitization, and potential future approaches to manipulating allorecognition.

Transplant Immunology: Host versus Graft and the Basis of Allorecognition

Generation of a significant immune response against the transplanted graft involves sequentially coordinated events. First, recognition of the graft as nonself is mediated by the innate and adaptive immune responses. In the setting of deceased donor organ transplants, the initiation of this cascade begins in the deceased donor. Brain death results in significant hormonal and physiologic changes that elicit a profound inflammatory response in individual organs resulting in cellular injury prior to the preservation process. Organ preservation followed by a prolonged period of cold ischemia, surgical implantation, and reperfusion of the transplanted organ result in ischemia-reperfusion injury (IRI). IRI is a complex process in which cells of the innate immune system; neutrophils, macrophages, and natural killer (NK) cells become activated, migrate to the transplanted organ, and engender a marked inflammatory response. This response triggers the activation and maturation of antigen-presenting cells (APCs), leading to antigen processing, presentation, and recognition by the cells of the adaptive immune system. Second, recognition of alloantigen leads to activation of

antigen-specific T and B lymphocytes. At this step, modern immunosuppression strategies have been successful in altering the intracellular signaling mediated by the T cell receptor (TCR) complex (calcineurin) and the inhibition of costimulatory molecules (belatacept, alefacept). Third, graft rejection ultimately occurs when the activated lymphocytes bring about direct cellular damage through effector cells that include monocytes, cytolytic CD8⁺ cells, and NK cells and by mediating B cell antibody-dependent cellular cytotoxicity (ADCC). In the following section, these three coordinated events are discussed in further detail.

ALLOANTIGEN RECOGNITION: INNATE AND ADAPTIVE IMMUNE RESPONSES

The innate immune system has evolved to be the first line of defense against invading microorganisms. APCs such as dendritic cells (DCs) are equipped with pattern recognition receptors (PRRs) that recognize specific molecules derived from different microorganisms known as pathogen-associated molecular patterns (PAMPs).¹ There are many types of PRRs, but the class most recently studied are Toll-like receptors (TLRs) found on the cell surface. TLRs are expressed on many cell types but are predominantly found on APCs, including macrophages, DCs, and B cells. They are also found on other cells of the innate immune system, including mast cells, basophils, neutrophils, and eosinophils.² When TLRs recognize bacteria- or virus-specific PAMPs, they trigger a proinflammatory response mediated by neutrophils, macrophages, and complement.³ The activation and maturation of DCs through these nonspecific receptor-ligand interactions result in the regulation of the adaptive immune response. Mature DCs secrete cytokines and chemokines, present alloantigen to T cells, and provide costimulatory molecules to the T cell, resulting in T cell activation and a profound alloimmune response to exogenous pathogen.^{4,5}

The innate immune system is also triggered by the binding of endogenous ligands that are released from damaged cells. These ligands, called damage-associated molecular patterns (DAMPs), bind and act in the same fashion as PAMPs.⁶ During the process of transplantation, cellular injury of the allograft occurs at multiple time points, and this damage results in the release of DAMPs into the circulation. After their release from necrotic cells, these ligands engage TLRs and induce an inflammatory response that results in the activation and maturation of DCs. These cells are now primed to regulate an adaptive immune response. When alloantigen is processed by mature DCs and recognized by T cells, T cell

activation occurs and a profound adaptive immune response follows. This has been demonstrated clinically in the setting of kidney transplantation, where deceased donor kidneys that sustain significant injury during the transplantation process and develop delayed graft function (DGF) demonstrate higher rates of rejection than those without DGF.⁷ In a clinical trial of cyclosporine-treated kidney transplant patients, intraoperative treatment of IRI with the free radical scavenger superoxide dismutase significantly reduced the incidence of acute rejection and early immune graft loss and improved long-term graft outcome. These findings demonstrate that nonspecific tissue injury to renal allografts can have a significant impact on the development of cellular rejection.⁵

Receptors of Adaptive Immunity

Histocompatibility and the human leukocyte antigen system In human immunity, recognition of foreign antigens is governed by the human leukocyte antigen (HLA) system. HLA represents the human equivalent of the major histocompatibility complex (MHC). HLA is encoded on chromosome 6, spans approximately 4 Mb, and contains more than 250 expressed genes, many of which have immune functions. The subpopulation of HLAs that do not generate a self-reactive response to host antigens is the same repertoire of HLAs that can recognize foreign antigens as short peptides. These HLAs bind donor antigens and mediate T cell signaling by self-restricted T lymphocytes. HLA polymorphism has evolved to efficiently bind and present the vast array of foreign antigens from infectious sources, cancerous cells (altered self), or donor organs. The variance in evolutionary pressures changes with geography and time, and HLA phenotypes differ across populations. The HLA genes with clinical relevance to donor-host matching are segregated into class I and class II. Although class III genes exist and encode complement factors C2, C4A, and C4B; tumor necrosis factor (TNF); lymphotoxin α and β ; heat shock proteins; and properdin factor B, these genes are not typically taken into consideration during the pretransplantation match run that identifies a recipient on the list for a given donor organ.

HLA class I genes cover an approximately 2 Mb region of chromosome 6 and encode the classic transplantation antigens HLA-A, HLA-B, and HLA-C. These antigens are normally constitutively expressed on almost all nucleated cells. Class I gene encodes a 44 kDa transmembrane heavy chain consisting of three extracellular domains (α_1 , α_2 , and α_3) that associates noncovalently with β_2 -microglobulin [see Figure 1]. The highly polymorphic distal α_1 and α_2 domains contribute residues to the peptide-binding cleft that regulates antigen recognition. The proximal α_3 domain that lies closest to the cell membrane is highly conserved and ligates CD8 expressed on T lymphocytes. This interaction confers HLA class I restriction on CD8⁺ T lymphocytes, which in turn regulates direct antigen presentation. Other class I loci (H, J, K, L, N, P, S, T, U, V, W, X, Y, Z) exist, but their function in clinical transplantation remains to be determined.

Class II HLAs consist of three primary loci: *HLA-DP*, *HLA-DQ*, and *HLA-DR*. In contrast to class I antigens, class II antigens are expressed only on B lymphocytes, activated T lymphocytes, and APCs (monocytes, macrophages, and dendritic cells). Class II antigen expression may be induced

on a variety of cell types during inflammation by regulatory cytokines, including interferon gamma and TNF- α . Class II genes encode a structurally different extracellular glycoprotein to class I. In class II, two separate transmembrane proteins, α and β chain, cooperate to regulate antigen recognition [see Figure 1]. The α_1 and β_1 distal extracellular domains form the peptide-binding cleft. The β_1 domains are highly polymorphic and control the repertoire of peptides that are recognized. The β_2 domain associates with CD4 on T lymphocytes with predominantly helper/inducer function and confers HLA class II restriction. This association between class II and CD4 regulates indirect antigen processing.

Direct and indirect antigen presentation This elaborate system of cell surface antigens provides two essential functions for regulating the host immune system. First, the extensive repertoire of class I and II HLAs contained on the host and donor serve as labels that allow distinction of “self” (host) from “foreign” (derived from donor, viral, bacterial, or transformed self). Second, HLAs function as binding elements for screening and recognizing peptide antigens. The expansion and deletion of self versus nonself HLAs occur during maturation in the thymus, where T cells that respond to self-antigens are deleted. This process is called negative selection. Alternatively, antigens specific for foreign peptides displayed by self-HLA molecules are allowed to expand. This process is called positive selection. These positively selected T cells recognize foreign HLA in allografts and induce graft rejection. In the context of clinical transplantation, the host immune system is specifically directed against foreign HLA and efforts directed to improve immunosuppression, prevent rejection, and prolong graft survival depend on manipulating these donor-host interactions.

The nature of the HLA molecules recognized by alloreactive T cells varies according to the pathway of alloantigen presentation. In turn, the activated pathways generate a distinct immune response. Direct alloantigen recognition occurs when T cells recognize foreign or self-peptides loaded onto donor HLA. APCs derived from the allograft “directly present” donor HLA found on the donor-derived APC cell membrane to alloreactive host T cells [see Figure 2a]. The T cells responding to direct antigen presentation recognize determinants on the allogeneic HLA molecule itself as well as structures composed of both donor-derived HLA and bound peptide. The peptides presented by foreign HLA molecules may be derived from either polymorphic proteins (HLAs) or nonpolymorphic proteins (enzymes, scaffolding, or structural proteins).

In contrast, the response to foreign peptides processed and loaded onto self-HLA is termed indirect alloantigen recognition. Indirect recognition first requires antigen processing and then presentation by recipient-derived APCs [see Figure 2b]. The indirect alloresponse is analogous to the immune response to invading microbes, which are also presented to T cells as peptides displayed by self-HLA molecules on host APCs. Acute rejection of an allograft is primarily dependent on direct alloantigen recognition. The ratio of T cells that are activated by the direct pathway to indirect pathway is estimated at 100:1. Alternatively, experimental evidence suggests that in chronic rejection, the dominant mechanisms are mediated by the indirect pathway. Given

Figure 1 Human leukocyte antigen (HLA). HLA class I is composed of three extracellular domains (α_1 , α_2 , and α_3) that associate noncovalently with β_2 -microglobulin (β_2 M). The α chains are highly polymorphic and contribute residues to the peptide-binding cleft. HLA class II is composed of α and β chains. The α_1 and β_1 distal extracellular domains form the peptide-binding cleft.

Figure 2 (a) Direct allorecognition. T cells responding to direct antigen presentation by donor-derived antigen-presenting cells (APCs) recognize determinants on the allogeneic HLA molecule as well as structures found on the bound peptide. (b) Indirect allorecognition. Indirect recognition requires antigen processing and presentation by recipient-derived APCs. HLA = human leukocyte antigen; TCR = T cell receptor.

that chronic rejection is a major cause of graft loss, further investigation and understanding of the indirect pathway may yield therapeutic approaches to prevent chronic rejection.

Minor histocompatibility antigens The major immunologic barrier to solid-organ transplantation (heart, lung, kidney, and pancreas) is primarily regulated by HLA. However, HLA does not define the full repertoire of antigens that can generate a response that culminates in rejection. Both human and murine studies have demonstrated that non-MHC molecules, referred to as minor histocompatibility antigens, can also mediate rejection. The clinical importance of minor antigens is demonstrated by the fact that HLA-matched siblings (unlike identical twins) require immunosuppression to prevent graft rejection. By definition, this alloresponse is targeting minor (or non-HLA) antigens. The mechanism of the alloresponse to minor antigens is similar to the response to microbial antigens in that host-HLA molecules present foreign peptides to host T cells (indirect presentation).

One example of a minor antigen is the major histocompatibility complex class I-related chain A (MICA) antigen. This antigen is structurally similar to MHC class I antigens and can be expressed on a variety of cells, including monocytes, epithelial cells, and endothelial cells. MICA is polymorphic and can elicit production of antibodies in transplant recipients, more so than the closely related major histocompatibility complex class I-related chain B (MICB antigen). The development of anti-MICA antibodies may be associated with worse graft survival, especially in recipients of well-MHC-matched kidneys.⁸

ACTIVATION OF ANTIGEN SPECIFIC T AND B LYMPHOCYTES

T Cell Response

Recipient T cells that react to donor antigen are critically important in the immunologic response that results in allograft rejection. T cell recognition of alloantigen is the primary event that leads to activation, proliferation, and differentiation of alloreactive T cells.

T cell receptor and intracellular signaling Host T cells do not directly bind and recognize isolated antigens. Rather, T cells recognize a complex composed of peptide fragment of foreign antigen bound to an HLA molecule, and this process confers HLA restriction on any antigen. Recognition of the peptide-HLA complex is then mediated by the TCR. Structural and genetic analysis of the TCR reveals significant homology with B cell immunoglobulin receptors. The TCR is composed of separate α and β chains encoded by loci on chromosomes 14 and 7, respectively. Each locus comprises a series of V, D, and J (variable) and C (constant) domains. Variability in the α -chain locus is conferred by V and J genes, whereas β -chain locus variability is mediated by V and D regions. These loci undergo rearrangements during T cell development, maturation, and differentiation, following the principles of gene arrangement and allelic exclusion to generate receptor diversity capable of recognizing an extensive repertoire of antigens.

T cells may also express alternative TCR γ and δ chains encoded on chromosomes 7 and 14, respectively. These chains are similar to α and β but demonstrate less diversity

and are structurally more similar to immunoglobulins. Interestingly, $\gamma\delta$ T cells can be found among the intraepithelial lymphocytes of the gastrointestinal tract, providing support to the theory that $\gamma\delta$ T cells contribute to immunologic surveillance of pathogens. Soluble forms of the TCR exist, resulting from alternative messenger RNA splicing or from proteolytic cleavage of surface receptors. The function of soluble TCR is not well understood.

Similar to surface immunoglobulin, the TCR is not expressed alone in the membrane. The TCR requires the coexpression of a complex of invariant chains termed cluster of differentiation 3 (CD3) [see Figure 3]. CD3 plays a significant role in proper TCR cell surface expression and TCR-mediated intracellular signaling. A monoclonal antibody to CD3, OKT3, was developed and approved to be used to treat severe T cell-mediated rejection in kidney and pancreas transplant recipients. Muromonab OKT3 binds to CD3 and inactivates T cells. This drug has been used less frequently over recent years as a result of systemic inflammatory responses seen with drug infusion. More recently, monoclonal antibodies that selectively bind to α and β chains of the TCR have been developed and are currently being studied in clinical trials in kidney transplantation. The hypothesis being studied is that by avoiding the inhibition of γ and δ chains of the TCR, the risk of infection will decrease while maintaining adequate prevention of rejection.

A variety of downstream intracellular signaling pathways have been identified in T cells that regulate the immune response to TCR activation. Key components of these pathways have also been targeted for use in immunosuppression. Ligation of the TCR results in phosphorylation of second messengers and activation of three principal biochemical pathways: calcineurin, protein kinase C, and Rac-mitogen-activated protein (MAP) kinase pathways [see Figure 4]. The primary function of calcineurin involves dephosphorylation of nuclear factor of activated T cells (NFAT), allowing NFAT to translocate from the cytoplasm to the nucleus. Once in the nucleus, NFAT binds to DNA regulatory sequences and increases the transcription of genes for several cytokines, including the T cell growth factor interleukin-2 (IL-2). Cyclosporine exerts its immunosuppressive effects by binding to cyclophilin, an intracellular protein, and the cyclosporine/cyclophilin complex subsequently inhibits the activity of calcineurin. Tacrolimus (FK506) binds to FK-binding protein (FKBP), and the tacrolimus/FKBP complex similarly inhibits the activity of calcineurin [see Figure 4].⁹ This class of drugs is termed calcineurin inhibitors (CNIs).

CD4 versus CD8 and T helper type 1 versus T helper type 2 Mature T cells can be distinguished by the presence of either CD4 or CD8 cell surface proteins (CSPs). CD8 molecules directly ligate HLA class I (through β_2 -microglobulin) and define the class I-restricted subset of CD8⁺ cytolytic T lymphocytes [see Figure 5a]. Alternatively, CD4 molecules directly bind HLA class II (through the β_2 subunit) and define the class II-restricted subset of CD4⁺ helper T lymphocytes [see Figure 5b]. In simplified terms, CD4⁺ T cells mediate the initial recognition of an alloantigen and help amplify and coordinate the subsequent immune response. Activated CD8⁺ T lymphocytes that have responded to these signals function as downstream effectors to eliminate threats to the host. This

Figure 3 T cell receptor (TCR) and CD3. The TCR is composed of α and β chains and requires the coexpression of a complex of invariant chains termed cluster of differentiation 3 (CD3). CD3 regulates proper TCR cell surface expression and TCR-mediated intracellular signaling. HLA = human leukocyte antigen.

Figure 4 T cell-associated second messenger signaling pathway. Key components of the T cell signaling cascade have been targeted for therapeutic immunosuppression. Adapted with permission from Halloran PF.⁹ AP = activator protein; CD = cluster of differentiation; CTLA = cytolytic T lymphocyte antigen; IKK = inhibitor of nuclear factor κ B kinase; MHC = major histocompatibility complex; MAP = mitogen-activated protein; MPA = mycophenolic acid; mRNA = messenger RNA; mTOR = mammalian target of rapamycin; NF = nuclear factor; NFAT = nuclear factor of activated T cells; PI₃K = PI₃ kinase; TCR = T cell receptor.

Figure 5 (a) CD8 molecules directly ligate class I human leukocyte antigens (HLAs), and this confers restriction to CD8⁺ cytolytic T lymphocytes. (b) CD4 molecules directly bind HLA class II and define the class II-restricted subset of CD4⁺ helper T lymphocytes. APC = antigen-presenting cell; CD = cluster of differentiation; TCR = T cell receptor.

functional division of labor between immune induction (CD4) and target cell lysis (CD8) is not definitive or mutually exclusive. For example, CD4⁺ cells restricted to class II can have cytolytic function in the appropriate cellular context. Similarly, CD8⁺ cells can produce many of the cytokines elaborated by CD4⁺ lymphocytes. Importantly, in a model of mouse heart transplantation, CD4-deficient mice are unable to reject grafts, whereas CD8-deficient mice have their rejection response intact.¹⁰ This is one of several models in which a CD4⁺ T cell-mediated delayed-type hypersensitivity (DTH) response is sufficient to cause rejection without requiring the cytolytic CD8 effectors. In contrast, data from other experimental models demonstrate that inhibition of CD8 by CD8 antibody alone prevents rejection, suggesting that functional CD8⁺ T lymphocytes are necessary but not sufficient.¹¹ Together, these data confirm the redundancy of the various components of the alloresponse and the highly conserved mechanisms that lead invariably to allograft rejection.

Activated CD4⁺ T cells produce different cytokine profiles according to the pathway by which cellular differentiation occurs. With specific antigenic stimulation, CD4⁺ T lymphocytes differentiate into either helper type 1 (Th1) cells or helper type 2 (Th2) cells. Th1 cells secrete cytokines, IL-2, interferon gamma, IL-12, and TNF. These cytokines stimulate DTH activity, cytolytic activity, and production of opsonizing and complement-fixing IgG antibodies. Th2 cells secrete cytokines that include IL-4, IL-5, IL-10, and IL-13. These cytokines are critical for the induction of humoral immunity, specifically stimulating the production of immunoglobulin E (IgE) and activating eosinophils.

The regulation of these two types of responses has been extensively studied in CD4⁺ helper T lymphocytes, but the dichotomous responses can also apply to CD8⁺ cytolytic cells. Activating stimuli for Th1 responses include interferon gamma and IL-12, whereas IL-4 promotes Th2 responses. Complementary inhibitory signals including interferon gamma-mediated downregulation of Th2 and IL-4-mediated inhibition of Th1 ensure that each pathway becomes increasingly polarized after the initial activation. Th1 responses have been hypothesized to mediate rejection, whereas Th2 responses have been implicated in tolerance, or decreased donor-derived T cell responsiveness. These generalizations have been derived from observations that Th1 cytokines promote damage to the graft via effector cell DTH and cytolytic activity, whereas Th2 cytokines antagonize these functions. Experimental studies have shown that acute rejection is associated with an expansion of Th1 cytokines, whereas prolonged survival is associated with reduced levels of these cytokines. However, other studies have shown that rejection is associated with the production of type 1 and type 2 cytokines, whereas tolerance is associated with a reduction in both types of cytokines.

For now, attempts to effect graft rejection by manipulating cytokines have been largely unsuccessful. However, ongoing studies continue to define new cytokines and their roles in immune responses. For example, a third type of cytokine profile has been reported in cells that produce IL-17. This Th17 response appears to have a strong inflammatory effect and may potentially become a target of antirejection therapies. Early involvement of IL-17 in the rejection of kidney

allografts has been shown in both murine and human models, and in the absence of the Th1 response, Th17 cells can clearly mediate transplant rejection.¹²

Costimulatory pathways The interaction between a given TCR and the unique epitopes on the HLA/peptide complex is antigen specific and determines the specificity of the immune response. However, efficient T cell activation requires other accessory cell surface molecules called costimulatory molecules to stabilize the TCR:HLA/peptide complex [see Table 1]. T cell activation requires one primary signal through the TCR and a second costimulatory signal through these accessory molecules. Costimulatory molecules stabilize the TCR by prolonging contact adhesion between the T lymphocyte and the APC, thereby providing time for the TCR to sample APC cell surface antigens. In addition, costimulation allows efficient transduction of the TCR-initiated signals that activate the calcineurin, MAP kinase, and nuclear factor κ B pathways. Multiple costimulatory molecules have been identified, but the most potent secondary signals regulating T cell clonal expansion and differentiation are provided by the CD28/B7 and TNF/tumor necrosis factor receptor (TNF-R) families of molecules.

CD28 is expressed on most T lymphocytes, and engagement of CD28 increases T cell proliferation by a variety of mechanisms, including the production of IL-2 and other cytokines. APCs express two ligands for CD28: B7-1 (CD80) and B7-2 (CD86). Upregulated expression of both B7 molecules occurs when APCs are activated by a variety of inflammatory stimuli, including microbial infection and cytokines. B7-1 and B7-2 can both provide T cell costimulation through

CD28 but have distinct patterns of expression and binding kinetics for CD28, suggesting significant differences in their roles. B7-1 and B7-2 also regulate T cells by binding cytolytic T lymphocyte antigen-4 (CTLA-4). In this fashion, CD28 provides a stimulatory signal, whereas CTLA-4 inhibits T cell proliferation. Targeting the CD28/B7 pathway can elicit antigen-specific unresponsiveness or T cell anergy that occurs only at the time of transplantation, allowing the recipient to be free of the effects of chronic long-term immunosuppression. In experimental models, blockade of B7 molecules on APCs has been shown to significantly prolong graft survival. However, in most in vivo models of B7 blockade, anergy assigned to specific antigens has been difficult to demonstrate, mostly because of the redundancy and complexity of costimulatory mechanisms. Induced costimulatory molecule (ICOS), programmed death-1 (PD-1), and B7-H3 represent other homologous members of the CD28/B7 family that exert a functional role in costimulation [see Table 1].

The TNF-R family is expressed on T cells and its ligand, TNF, is expressed on complementary APCs. The TNF-R also regulates dual functions with death domain (DD)-mediated apoptosis on the one hand and TNF-R associated factor (TRAF)-mediated T-cell activation representing the other extreme. APC-derived CD40 receptor and its corresponding T cell ligands, CD154 and CD40L, belong to the TNF and TNF-R superfamilies and play a critical role in T cell costimulation. CD40 engagement activates B cell antibody production, DCs, and monocytes and upregulates expression of the B7 family of molecules during antigen presentation.¹³ Blockade of the CD40/CD154 pathway in experimental models of transplantation has proven to be extremely effective in

Table 1 Costimulatory Molecules

T Cell	APC	Comments	Study
CD28	B7-1 (CD86) B7-2 (CD80)	B7-1 and B7-2 can both provide T cell costimulation through CD28	Acuto and Michel ⁴⁴
PD1	PDL-1, PDL-2	PD-1 can be induced on CD4 ⁺ , CD8 ⁺ T, NK, and B cells and monocytes, and ligation delivers an T cell inhibitory signal	Durrbach et al ¹³
CTLA4	B7-1(CD86) B7-2 (CD80)	CTLA-4 binding by B7-1 and B7-2 inhibits T cell proliferation	Larsen et al ⁴⁵
ICOS	ICOS-L, B7h	In experimental studies, anti-ICOS blocking mAb can significantly prolong allograft survival	Ozkaynak et al ⁴⁶
CD28	B7-H3	B7-H3 is induced in dendritic cells; monocytes; and T, B, and NK cells and increases T cell proliferation	Steinberger et al ⁴⁷
TNF-R	TNF	The TNF-R regulates dual T cell functions through apoptosis and also TRAF-mediated T cell activation.	Durrbach et al ¹³
CD40L, CD154	CD40	CD40 engagement activates B cell antibody production and upregulates expression of the B7 family	Durrbach et al ¹³
OX40	OX40L	OX40 is expressed on activated CD4 and the Th2 T cells and activates B cell proliferation	Acuto and Michel ⁴⁴
CD27	CD70	CD27 activation induces high levels of IL-2 and TNF- α Blockade of CD27 may prevent chronic allograft vasculopathy	Yamada et al ⁴⁸

CD = cluster of differentiation; CTLA = cytolytic T lymphocyte antigen; ICOS = induced costimulatory molecule; IL-2 = interleukin-2; mAb = monoclonal antibody; NK = natural killer; PD = programmed death; Th2 = T helper type 2; TNF- α = tumor necrosis factor- α ; TNF-R = tumor necrosis factor receptor; TRAF = tumor necrosis factor receptor associated factor.

preventing graft rejection. Other members of the TNF-R/TNF family include CD27, OX40, and OX40L [see Table 1]. Clinical applications of costimulatory blockade are discussed below.

B Cell Response

Hyperacute rejection and antibody-mediated rejection The importance of B cells and antibodies in the rejection of an allograft is most dramatically illustrated by hyperacute rejection. This process occurs within minutes and up to 24 hours after transplantation in patients who were previously sensitized and had developed antibodies to ABO blood group antigens or to allogeneic HLA molecules. This most commonly occurs in patients who have had previous transplants, blood transfusions, or pregnancies. During the previous era, hyperacute rejection became a rare phenomenon because ABO blood typing and crossmatching detected these critical antibodies. Delayed antibody-mediated rejections (AMRs) occurring later than 24 hours after transplantation were described as a result of either the presence of low antibody levels missed by low-sensitivity crossmatching techniques or the reactivation of memory B cells. However, AMR has become more prevalent in the current transplant era as a result of increased rates of transplantation in highly sensitized patients. In reality, mixed cellular and antibody-mediated rejection probably represents a spectrum of immunologic reactions as the genesis of one may be determined by the other. The cellular component (mediated by T cells) induces antibody elaboration (mediated by B cells) that can lead to allograft destruction. This antibody component of rejection is characteristically identified in biopsy specimens by the deposition of the C4d complement protein from the classic complement pathway. Although the histologic findings in these cases are variable, the presence of C4d in the peritubular capillaries of kidney allografts with evidence of circulating donor-specific antibodies (DSAs) correlates closely with AMR. Antibodies may also play an important role in chronic rejection (see below). Both acute and chronic AMR can potentially be treated with biologic agents that target the B cell-specific marker CD20.

EFFECTOR PATHWAYS FOR CELLULAR DAMAGE

Once CD4⁺ T cells recognize foreign class II HLA molecules, they play a critical role in regulating various areas of the effector response. The initial innate immune inflammatory response to the injury associated with transplantation is antigen independent. The antigen-specific activation of CD4⁺ T cells leads to expression of cell surface molecules and production of cytokines that in turn stimulates monocytes. This cooperation between CD4⁺ T cells and monocytes, or DTH response, plays an important role in the destruction of a graft.

The activation of CD4⁺ T cells and production of cytokines also stimulate activation and proliferation of both cytolytic CD8⁺ T cells and NK cells. On recognition of HLA class I molecules on allograft cells, CD8⁺ T cells cause cell death by two main mechanisms. First, the release of soluble cytotoxic factors such as granzymes and perforin causes direct damage on target cells. Second, the upregulation of Fas ligand on T cells, which finds Fas receptor (CD95) on target cells, initiates a death signal or cascade. Ligation of FAS on CD95

receptor found on cells of the allograft initiates apoptosis or programmed cell death.

Cytokines that are released by CD4⁺ T cells also stimulate B cells. On binding of specific antigen by the B cell receptor or cell surface immunoglobulin, B cells proliferate and differentiate into plasma cells. Plasma cells release soluble immunoglobulins, or antibodies, which subsequently bind allogeneic cells. Antibodies can cause cell damage by fixing complement and mediating ADCC.

Clinical Management of the Transplanted Allograft

DONOR GRAFT–RECIPIENT HOST MATCHING

A favorable clinical outcome after solid-organ transplantation relies on obeying defined immunologic principles. Graft rejection is regulated by recipient lymphocytes that recognize CSPs from donor tissue. Allograft CSPs are categorically different from recipient CSPs, and this discrimination of self from nonself triggers the series of reactions that lead to antigen-specific, immune-mediated rejection. Specifically, the two major categories of CSPs include ABO blood group and HLAs.

The importance of matching these CSPs between donors and recipients varies based on the organ that is transplanted. In kidney transplantation, increasing HLA mismatching between donor and recipient has been associated with increased rates of rejection and decreased allograft survival. As a result, donor-recipient HLA matching is incorporated into the deceased donor kidney allocation algorithm. However, HLA mismatching in liver transplantation has not been shown to significantly impact graft survival and therefore is not used as part of the liver allocation scheme. Clearly, the precise immunologic risk varies not only with the immunologic determinants in each donor-recipient pair but also according to the antigenicity of the type of organ transplanted. In the following section, we describe (1) optimal immune matching between donor and recipient using ABO and HLA type, (2) the techniques used to define HLA type and to assess immunologic risk in the recipient, and (3) current methods used for desensitization.

ABO Blood Group and ABO-Incompatible Transplantation

In most cases of organ transplantation, donor-recipient matching involves consideration of ABO blood group compatibility. The vast majority of solid-organ transplantations occur with ABO-identical blood type matching. ABO-nonidentical but ABO-compatible organ transplantations occur and are successful, as is the case with a blood type O donor organ transplanted to a non-O recipient [see Table 2]. When transplantations are performed across these ABO barriers without highly specialized desensitization protocols, hyperacute rejection is expected to occur. In selected cases, A₂ kidney donors can be safely used in non-A recipients such as B or O recipients. This, in part, is attributable to the diminished antigenicity of the A-antigen in A₂ donors, so recipients with an anti-A titer less than 1:32 can be considered for successful transplantation.¹⁴

Transplantation using ABO-incompatible allografts was developed as a potential solution for the problem of organ shortage, increasing waiting times, and high mortality on the

Table 2 ABO Blood Group Compatibility for Solid-Organ Transplantation	
Recipient Blood Group (IgM) with Associated Antibodies	Compatible Donors
A (anti-B)	A, O
B (anti-A)	B, O
AB (none)	A, B, AB, O
O (anti-A and anti-B)	O

renal transplant waiting list. Using living related donors, successful ABO-incompatible transplants have been performed in over 1,000 patients in Japan.¹⁵ In North America, an analysis of the United Network for Organ Sharing (UNOS) registry data for centers performing single-kidney ABO-incompatible transplantations with pretransplantation antibody removal has shown that long-term graft survival can be comparable to ABO-compatible kidney transplantations.¹⁴ However, many centers have reported an early and significant immunologic risk, with approximately 10 to 30% of patients developing acute AMR and approximately 10% of patients experiencing early graft loss.¹⁶ These types of specialized transplantations should be considered only at centers using protocols dedicated to pretransplantation removal of antibodies. Desensitization for ABO incompatibility is currently being performed according to protocols based on (1) high-dose intravenous immune globulin (IVIg) treatment and (2) combinations of plasmapheresis and low-dose IVIg.¹⁷ Improvements in these strategies will need to address the problem of early graft loss, early rejection rates, and the subsequent impact on long-term outcomes.

HLA Typing: Serologic Typing versus DNA-Based Techniques

HLA functions as the predominant cell surface protein that is targeted for immune detection. As previously stated, the utility of HLA matching between donor and recipient is organ specific and most critical in kidney and pancreas transplantation. Matching for class I HLA-A and HLA-B and class II HLA-DR MHC antigens has historically had the most profound effect on increasing allograft and patient survival. Seminal studies by Patel and Terasaki determined that crossmatch-positive recipients observed a graft failure rate of 80% within 2 days after kidney transplantation compared with only 4% in crossmatch-negative patients.¹⁸ Currently, the beneficial effects of HLA matching are based on compatibility at the *HLA-A*, *HLA-B*, and *HLA-DR* loci. Although multiple factors regulate transplant outcomes, optimal graft survival is achieved in transplants that have no donor-recipient HLA mismatches (zero mismatch). Transplants with a match at the *HLA-DR* locus (while allowing mismatches at the other loci) also have increased survival outcome. Decreased allograft and patient survival resulting from HLA mismatch has been tempered with significant improvements in immunosuppression.

A variety of clinical tests have evolved for characterizing HLA type. These are based on either serologic tests or molecular DNA sequencing methods. The specificity and precision of HLA typing are a function of the technique employed.

DNA techniques have largely supplanted serologic tests. Traditionally, HLA typing was determined using the serologically based complement-dependent cytotoxicity (CDC) test. In this assay, HLA molecules are detected on the surface of separated T cells (HLA class I) and B cells (HLA class II) by obtaining lymphocytes from the patient. Activating antigens, derived from panels of sera from either multiparous women or multiple local volunteers, are then combined with these separated lymphocyte lineages. Once complement is added to the mix, the resulting damage to the lymphocyte membrane is detected by the uptake of vital dye and forms the basis of this cytotoxic test.¹⁹ The disadvantages to this test include the need for obtaining functional lymphocytes in the form of tissue, maintaining serum that is representative of the given donor population, and, ultimately, a low typing resolution inherent in the test.

DNA-based molecular methods employing sequence-specific polymerase chain reaction (SSP), sequence-specific oligonucleotide probes (SSOP), reference strand conformation (RSCA), or sequence-based typing (SBT) provide a number of advantages to CDC and represent the current standard of care. Live lymphocytes are not required, and DNA is easily extracted and stored from any nucleated cell. In these assays, DNA probes replace the role of the antisera used in the CDC test and the need for renewing pooled serum becomes unnecessary as the DNA reagents are easily replenished. Typically, peripheral blood lymphocytes are used as the source of DNA. Each of these methods employs polymerase chain reaction (PCR) amplification with primers or oligonucleotides, and they differ primarily in their resolution of the DNA typing. For example, SSP is rapid, capable of detecting allele groups, and considered a “low-resolution” technique as it is inefficient at achieving allele-level typing. SSOP uses short oligonucleotide DNA probes and is useful for typing large numbers of samples in batches. A variant of this technique uses probes coupled to fluorescence-labeled microbeads in a flow cytometric assay using X-Map technology (Luminex, Austin, TX).¹⁹ SBT provides high fidelity and resolution as are typically used to achieve allele-level HLA typing as required for stem cell transplantation programs.

Pretransplantation Alloantibody Detection, Crossmatching, and Immunologic Risk

In addition to HLA typing, the detection of pretransplantation alloantibodies in the recipient directly affects outcomes after transplantation. Sensitization against donor HLAs arising from pretransplantation pregnancies, blood transfusions, or prior transplantation can elaborate antibodies from recipient memory cells at the time of transplantation. Circulating antibodies primed in this fashion prior to transplantation may result in hyperacute or accelerated acute rejection after reperfusion of the implanted graft. These deleterious effects of AMR can be avoided by screening for DSAs in the recipient. These assays are generally based on (1) membrane-based/peripheral cell line-based testing (CDC, flow cytometry) or (2) solid-phase testing involving HLA affixed to particles in the form of multiplex bead or single antigen bead. These are limited in that many of them are not quantitative, are not functional, or are overly sensitive, with batch-to-batch variation between tests. The technical variations can be broad, with false positive and negative results built into the assays.

Finally, many of these assays do not evaluate non-HLAs. In this section, we briefly describe the various assays that can screen for antibodies.

CDC assay In addition to being used as a serologic test for HLA typing, the CDC assay can be used to determine the presence of alloantibodies in the recipient. As described above, the CDC test relies on live separated T cells for class I antibody identification and live B cells for class I and class II antibody detection in tests performed against the intended recipient's serum. The CDC assay is relatively inefficient and involves testing several panel donors to cover all major specificities or relying on commercially available frozen cell trays or immortalized lymphoblastic cell lines. These panel cells are not donor specific, and this particular application of the CDC assay for antibody detection should not be confused with the CDC "crossmatch" (see below). A major limitation with the CDC assay is that it can only detect complement-fixing antibodies.

Enzyme-linked immunosorbent assay Enzyme-linked immunosorbent assay (ELISA)-based methods use antigens that have been stripped off cells for the detection of HLA class I and II. These assays have an advantage over cell-based tests as large numbers of cells do not have to be collected and separated and a variety of antibodies, including non-complement-binding antibodies, can be detected. In addition, testing is efficient and fast (< 2 hours), and HLA antibodies can be specifically targeted [see Figure 6]. ELISA screening is capable of screening large numbers of patient samples in a

short period of time with a higher sensitivity than the CDC assay. However, the physical stripping of antigens from cells may promote conformational changes that do not reflect the in situ clinical function of an individual antibody-antigen couple.

Flow cytometry/X-Map assay These assays currently represent the gold standard for detecting and identifying deleterious alloantibodies. Soluble or recombinant HLA molecules are bound to polystyrene particles, and patient serum is mixed together to allow antibody-antigen binding. Particles are stained with varying amounts of two fluorochromes to facilitate identification, and a second antihuman antibody linked to a reporter molecule is then added to the reaction mixture, with measurement of reporter fluorescence as a quantification of antibody [see Figure 6]. X-Map and flow cytometric assays have the advantage of detecting both complement-fixing and non-complement-fixing antibodies. They can independently identify HLA class II specificities in the context of class I, and specific single antigenic alleles can be discriminated to allow precise determination of acceptable HLA mismatches. One drawback to this technique is that the HLAs are in a conformation altered from what occurs in situ, and this technique may identify antibody-antigen binding matches that have no clinical significance.

Patient-donor crossmatch Prior to any kidney transplantation, it is necessary to perform a functional assay or crossmatch to determine that no clinically significant donor-specific antibodies are present in the recipient-donor pair

Figure 6 Detection of alloantibodies by enzyme-linked immunosorbent assay (ELISA) or flow cytometry. HLA = human leukocyte antigen.

being considered. Crossmatching is normally performed using one or both of the following methods: (1) CDC crossmatching and/or (2) crossmatching by flow cytometry. In CDC crossmatching, recipient serum samples containing potential DSA are incubated with separated T and B cells from the intended organ donor. In this mixture, if antibody is bound to T or B cells, the addition of complement will result in donor cell lysis, yielding a “positive” crossmatch.¹⁸ T cell–positive crossmatches are usually attributable to anti-HLA class I antibodies and should preclude transplantation. B cell–positive crossmatches (in the absence of T cell positivity) may refer to either HLA class II antibodies or weak class I antibodies. This assay almost completely eliminated the hyperacute AMR response that can occur within minutes to hours after graft reperfusion. However, this original technique was relatively insensitive and early graft loss continued to occur in a minority of patients with a negative crossmatch. This assay was also limited by its inability to distinguish between HLAs and non-HLAs.

Some antibodies bind strongly to target cells yet poorly fix complement and therefore may not be picked up with the standard CDC crossmatch. These antibodies are still relevant in transplantation as they can cause cell damage through other immune mechanisms. The ability of the CDC crossmatch to identify these antibodies has been augmented by adding antihuman globulin (AHG) prior to adding complement in the CDC crossmatch assay [see Figure 7a]. The AHG crosslinks IgM or IgG antibodies, enhances the binding of complement, and thus increases the sensitivity of the CDC crossmatch assay.^{20,21}

Crossmatching by flow cytometry (FC-XM) is more sensitive than the traditional CDC approach. In this technique, donor lymphocytes are incubated with the recipient sera, and after washing, antihuman IgG (with fluorochrome stain conjugated) is added to the mixture. Additional antibodies (conjugated with a different fluorochrome) are added to identify either T or B lymphocytes. Flow cytometry then interrogates the mixture [see Figure 7b]. This technique is not reliant on complement activation for detecting antibodies and can be more than 10 times as sensitive as the CDC assay.²² Optimal decisional making is achieved after combining data from both CDC and FC-XM assays as some donor-recipient pairs may be FC-XM positive but CDC negative as a result of the highly sensitive nature of the FC-XM assay. The FC-XM is widely regarded as the most sensitive test for assessing the presence of DSA and is the gold standard in most transplant centers in the United States.²³ One drawback to the FC-XM is the lack of specificity with determining clinically relevant antibodies, and this assay may rule out transplantation between compatible donor-recipient pairs.²⁴

Recently, virtual crossmatching, whereby the HLA type of the donor is compared with the recipient’s HLA-antibody specificities determined by solid-phase assays,²⁵ is being investigated as a predictive tool to use in place of CDC or FC-XM. This assay does not require mixing between donor lymphocytes and recipient serum. Correlation of the virtual crossmatch with FC-XM was approximately 85% in reported studies.²⁶ Although its utility and precision in replacing the FC-XM are debated, it does provide an expedited screening tool for assessing organ allocation so that centers can rapidly screen donors who would likely yield a positive crossmatch

and allow the organ to be quickly allocated to a more appropriate recipient at another center.

CLINICAL MANAGEMENT OF GRAFT REJECTION

Although a thorough discussion regarding the management of transplant graft rejection is beyond the limits of this chapter, we discuss some of the clinical applications of the concepts described in the first part of this chapter in the following section. The different types of allograft rejection and common immunosuppressive medications are discussed.

Hyperacute, Acute, Accelerated, and Chronic Rejection

Prior to the establishment of the Banff working schemas, rejection of the renal allograft was traditionally classified into the following four categories: (1) hyperacute, (2) accelerated acute, (3) acute, and (4) chronic. Hyperacute rejection was defined as immediate rejection (minutes to hours) after reperfusion as a result of the presence of preformed antibodies. These alloreactive antibodies bind HLAs on the vascular endothelium of the allograft, leading to complement deposition and rapid graft thrombosis. As mentioned above, the sensitivity of both ABO testing and pretransplantation HLA crossmatching has traditionally precluded hyperacute rejection, which usually only otherwise results from clerical or technical errors in the crossmatch process. Currently, the risk of hyperacute rejection has increased because of the higher frequency of transplantations performed in sensitized patients and across immunologic barriers. Treatment for hyperacute rejection invariably involves transplant nephrectomy.

Accelerated acute rejection was defined as rejection occurring within 5 days of transplantation as a result of the formation of antibodies from activated memory B cells or the generation of cytotoxic T cells. Acute rejection was defined as rejection occurring after 5 to 7 days to weeks after transplantation as a result of alloantigen-specific activated T cells. This injury pattern can also be seen out to 12 months after transplantation. Chronic rejection was defined as slow progressive graft dysfunction starting after 3 months as a result of a combination of antibody-mediated and T cell–dependent cellular damage. This injury ultimately led to a phase of tissue remodeling stimulated by cytokines resulting in allograft dysfunction.

The Banff working group of pathologists, nephrologists, and transplant surgeons who standardized the nomenclature and classification of renal allograft pathology has met at regular intervals from 1993 to the present to update our working definition of transplant allograft rejection. Within the current definitions, the notions of hyperacute, acute, and chronic have been largely replaced by pathophysiologic and histologic classifications based on either acute AMR, T cell–mediated rejection, or chronic allograft rejection and nephropathy.²⁷ For example, a diagnosis of acute AMR of a kidney transplant requires the presence of C4d, a split-product of C4 from the classic complement cascade, morphologic evidence of acute tissue injury, and the presence of circulating DSAs. Acute T cell–mediated rejection is categorized based on whether the infiltration of lymphocytes is localized to the interstitium (stage IA: moderate tubulitis; stage IB: severe tubulitis) or involving the arteries as well (stage IIA: mild to moderate intimal arteritis; stage IIB: severe intimal arteritis; stage III: transmural arteritis with fibrinoid changes and necrosis of

Figure 7 Recipient-donor crossmatch. (a) The sensitivity is enhanced by adding antihuman globulin (AHG) prior to adding complement in the complement-dependent cytotoxicity (CDC) crossmatch assay. (b) Crossmatching by flow cytometry is not reliant on complement activation for detecting antibodies and can be severalfold more sensitive than the CDC assay. PBMC = peripheral blood mononuclear cells.

smooth muscle cells with lymphocytic inflammation). Chronic active T cell-mediated rejection, usually termed “chronic allograft arteriopathy,” is characterized by arterial intimal fibrosis with mononuclear cell infiltration and the formation of neointima within the graft. Kidney allograft biopsies may also demonstrate interstitial fibrosis and tubular injury without a specific etiology, and these are graded as mild, moderate, or severe depending on the percentage of kidney cortex that is involved.²⁷ Use of these new classifications of immunologic injury to the renal allograft is the current standard of care, and they have essentially supplanted the previous categories, which were more focused on the timing

of the injury. Future therapies for rejection will be guided based on these updated criteria.

Cellular Rejection versus Antibody-Mediated Rejection

Transplant allograft rejection is defined by a combination of clinical features and characteristic histologic findings. As described above, hyperacute rejection, mediated by preformed antibodies, presents as a blue-black kidney with poor tissue turgor immediately after reperfusion. The kidney can subsequently swell with medullary congestion, cortical necrosis, and vessel thrombosis. Urine output is either never established or drops off precipitously. Histologic analysis will

reveal polymorphonuclear lymphocytes in the glomeruli, fibrin deposition, and platelet thrombi.

In the hours to days after transplantation, delayed hyperacute rejection or accelerated acute rejection can occur and is best characterized by positive C4d immunostaining on vascular endothelium from the allograft biopsy, with or without the features of lymphocytic infiltration, tubulointerstitial neutrophils, or acute tubular necrosis as seen in classic cell-mediated rejection [see Figure 8]. C4d deposition in peritubular capillary endothelium is a marker for complement activation associated with humoral rejection and currently represents the only specific indicator of AMR. The presence of C4d staining in the peritubular capillaries with evidence of DSA supports the diagnosis of AMR. DSA can be demonstrated pretransplantation or be shown to have developed subsequent to reperfusion often by using the solid-phase X-Map assays described above.

Acute T cell-mediated rejection of the kidney typically occurs in the weeks to months following transplantation. The most common presentation is an asymptomatic patient with a greater than 10% rise in serum creatinine above baseline. In addition, some patients will present with decreasing urine output, fluid retention, peripheral edema, and proteinuria. Patients may have low-grade fever or tenderness over the graft, but most commonly they are asymptomatic. The workup of these patients should include a detailed history determining exposure to infections, compliance with medications, and recent illnesses that may have contributed to prerenal azotemia [see Figure 9]. Trends of recent immunosuppressive drug levels can help determine the relative risk of rejection and the possibility of calcineurin toxicity and guide the surgeon's index of suspicion. Duplex ultrasonography of the transplanted allograft should be performed to document the patency of vessels and rule out a vascular cause of organ dysfunction. The sonogram also provides anatomic information, including the presence of hydronephrosis caused by either an ischemic ureteral stricture or external ureteral compression by an adjacent lymphocele. When rejection is suspected, allograft biopsy is performed and will provide an assessment of the presence and severity of cellular rejection.

In addition to the histologic features of cellular rejection, the biopsy should also be evaluated for C4d deposition to assess for AMR as this may uncommonly present later after transplantation. Appropriate correlation with DSA should be made in conjunction with the biopsy results.

Immunosuppressive Therapies

Induction agents A variety of agents are available for induction immunosuppression, and currently their selective use is based on an assessment of the recipient's risk of rejection for the intended allograft. In reality, the choice of induction agent is institution specific as definitive level 1 long-term data (with follow-up > 15 years) comparing different regimens and their outcomes do not exist.

Antithymocyte globulin Thymoglobulin is a rabbit-derived, antithymocyte globulin used for the treatment of acute rejection. Its mechanism of action involves blocking CD2, CD3, and CD45 and altering T cell function and ultimately leads to depletion of peripheral blood lymphocytes. When used as an induction agent for 3 to 10 days, thymoglobulin can establish profound T lymphocyte depletion that lasts beyond a year.^{9,28} Side effects can include cytokine release, serum sickness, anaphylaxis, leukopenia, and thrombocytopenia. Typically, it is infused over a period of 4 to 8 hours in a central vein with preadministration of acetaminophen and corticosteroids for prophylaxis against fever and allergic reactions. Because of thymoglobulin's profound T cell depletion, serious late sequelae can include cytomegalovirus infection and posttransplantation lymphoproliferative disease (PTLD). The overwhelming lymphocyte depletion and significant infective risk that results from thymoglobulin administration has raised questions over which population of recipients would benefit most from its administration.²⁹ A shorter duration of treatment has been shown to be efficacious in low-risk kidney transplant recipients.³⁰ In addition, in patients with DGF who have an increased risk of rejection, the 5-year incidence of acute rejection has been demonstrated to be lower in patients treated with rabbit antithymocyte globulin than among those treated with basiliximab.³¹

Figure 8 Histopathology of kidney allograft with antibody-mediated rejection. Immunohistochemical staining showing C4d complement deposition on renal peritubular capillaries is associated with humoral rejection after transplantation. In normal kidneys, C4d is detectable in the glomerular mesangium and at the vascular pole. Reproduced with permission from Pascual J et al.⁴⁹

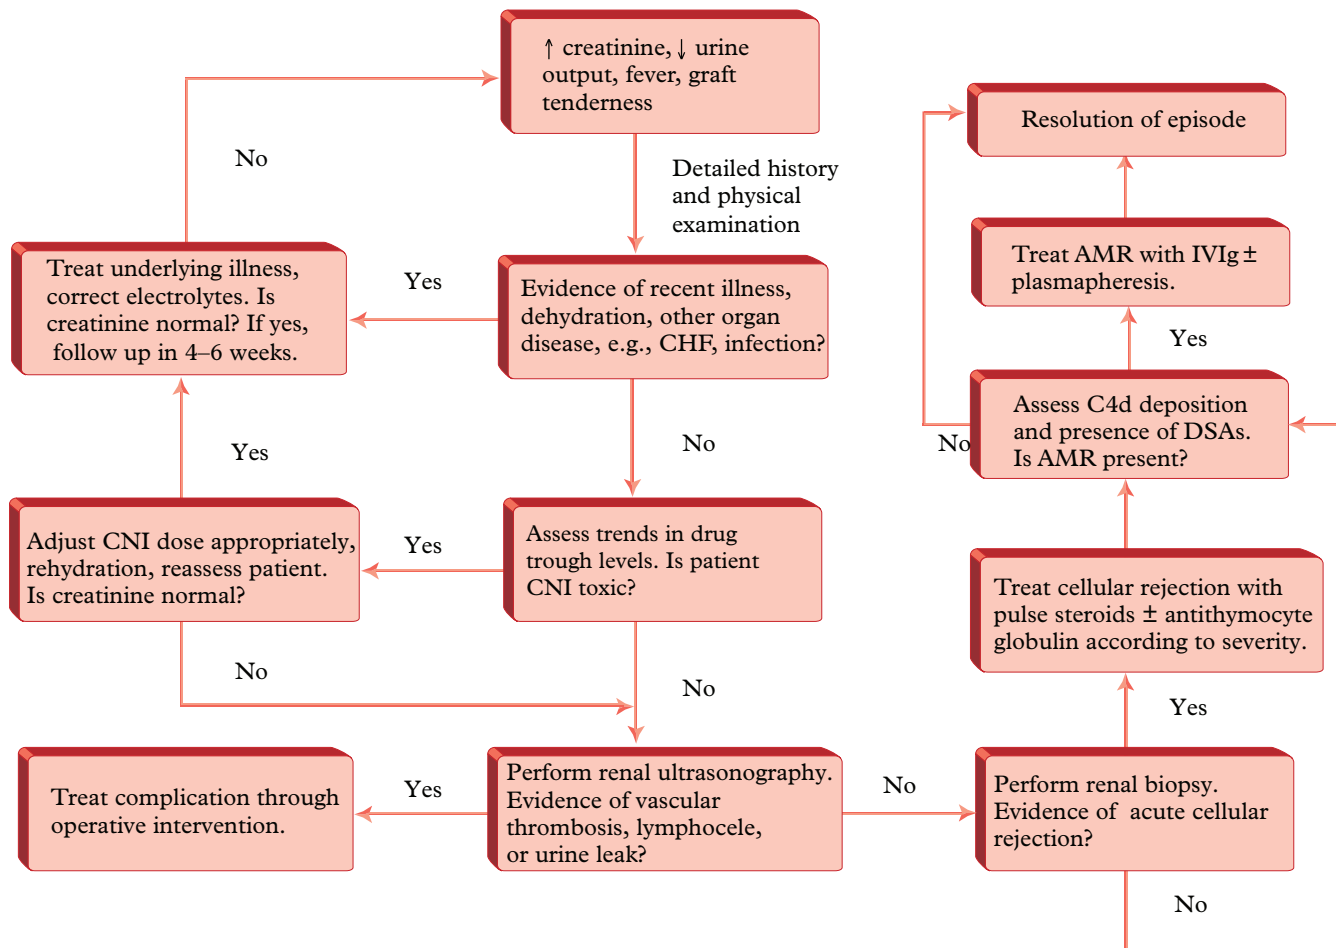

Figure 9 Algorithm for the assessment and management of renal allograft rejection. AMR = antibody-mediated rejection; CHF = congestive heart failure; CNI = calcineurin inhibitor; DSA = donor-specific antibody; IVIg = intravenous immune globulin.

Anti-CD25 monoclonal antibodies The prototypes for this class include basiliximab and daclizumab. Daclizumab was recently withdrawn from clinical use in transplantation. These anti-CD25 monoclonal antibodies that target the α chain of the IL-2 receptor on T cells and inhibit IL-2-mediated T cell proliferation on binding were designed to prevent rejection and not to treat active rejection. Typically, they are used in combination with other maintenance immunosuppression medications, such as CNIs and corticosteroids (see below). The advantages of basiliximab include its low immunogenicity, relatively long half-life in peripheral blood, low first dose-associated reactions, and the lack of need for drug-level monitoring. Administration of basiliximab at two 20 mg intravenous doses, preoperatively and then on postoperative day 4, produces saturation of the IL-2 α receptor sites for 30 to 45 days.³² This induction agent is best used in patients who have a low risk of graft rejection.³³

Alemtuzumab and rituximab Other agents used for lymphocyte depletion include alemtuzumab and rituximab. Their use in solid-organ transplantation remains controversial and should be reserved for selected patient populations. Alemtuzumab is a humanized monoclonal antibody used in the treatment of B cell chronic lymphocytic leukemia. It acts against CD52 and functions by causing cell lysis with prolonged and

significant depletion in a wide variety of immune cells. It use has been expanded as an induction immunosuppressive agent in kidney transplantation. The initial hope for its use was that it would allow for the development of immunosuppression protocols that would allow for sparing or avoidance of CNIs or corticosteroids.³⁴ Subsequent studies have shown a higher incidence of AMR in simultaneous kidney and pancreas transplant recipients receiving alemtuzumab.³⁵ Definitive, controlled trials are needed to establish the optimal dosing, long-term safety, and efficacy of alemtuzumab in transplant recipients.

Rituximab is a monoclonal antibody raised against CD20 that eliminates most B cell populations. It is approved for treating non-Hodgkin B cell lymphomas and was initially used in transplant recipients for treating PTLN.⁹ Currently, rituximab is used off-label in combination with plasmapheresis, IVIgG, and maintenance immunosuppression to treat deleterious alloantibodies.³⁶ It is unclear if the additional use of rituximab with plasmapheresis and IVIgG provides a significant benefit over plasmapheresis and IVIgG alone in the treatment of AMR in kidney transplant recipients.

Maintenance immunosuppression The choice of maintenance immunosuppression regimen varies from center

to center. The general strategy involves combining synergistic medications to maximize suppression while minimizing systemic toxicity.³⁷ Many regimens include the use of an antiproliferative agent (e.g., mycophenolate, sirolimus, everolimus), a CNI, and corticosteroids. Although azathioprine was the mainstay of antiproliferative agents in early regimens, it has now been largely replaced by mycophenolate.

Mycophenolate inhibits inosine monophosphate dehydrogenase (IMPDH), a critical enzyme in purine synthesis, and is available as mycophenolate mofetil (MMF; CellCept, Roche) or enteric-coated mycophenolate sodium (MPA; Myfortic, Novartis). MMF is a prodrug and requires conversion to the active compound MPA. Lymphocytes rely on de novo purine synthesis because salvage pathways for generating guanosine nucleotides are absent. Therefore, MPA selectively blocks T and B lymphocyte proliferation. The most common side effects include gastrointestinal distress, most notably diarrhea, and leukopenia.

Other antiproliferative agents include the mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus. Sirolimus (Rapamune) is a macrolide antibiotic, structurally similar to tacrolimus, that binds FKBP-12 and inhibits mTOR, resulting in cell cycle arrest in the G₁ to S transition. Everolimus (Certican) has comparable function but has a shorter half-life. Although the efficacy of sirolimus has been demonstrated in randomized clinical trials in kidney transplantation, large, prospective, randomized trials have not directly compared MMF with sirolimus. The adverse effects of sirolimus include hyperlipidemia, impaired wound healing, and nephrotoxicity associated with potentiation of CNI toxicity. If CNIs are used in conjunction with sirolimus, the CNI dose should be reduced. Sirolimus has also been associated with higher rates of wound complications and hernias and is usually avoided until complete wound healing has occurred.

CNIs revolutionized the field of transplantation and allowed long-term graft survival that made solid-organ transplantations an acceptable form of therapy for end-organ failure. As described above, the two prototypical agents, tacrolimus and cyclosporine, bind intracellular FKBP and cyclophilin, respectively, to inhibit T cell production of IL-2 [see Figure 4]. Toxicities associated with CNI include neurotoxicity, nephrotoxicity, hypertension, hyperglycemia, and hyperlipidemia. Cyclosporine-associated hirsutism and gingival hyperplasia may prevent its use in certain patients, whereas tacrolimus-associated hyperglycemia and alopecia may also be limiting. Drug levels are monitored with both tacrolimus and cyclosporine to maximize immunosuppression and minimize potential toxicities from elevated levels.

Corticosteroids continue to be an important component in most immunosuppressive regimens used in solid-organ transplantation and are often used as first-line therapy to treat rejection.³⁷ Corticosteroids function through multiple mechanisms to provide immunosuppression. Steroids are lymphotoxic; limit lymphocyte distribution; inhibit IL-1, IL-2, IL-3, IL-6, TNF- α , and interferon gamma; and decrease antigen presentation by inhibiting DCs. Steroids mediate these functions by intracellular diffusion and binding to glucocorticoid response elements found on the promoter regions of critical cytokines. In liver transplantation, an intraoperative bolus of intravenous steroids is commonly used as the primary

induction agent. Adverse effects associated with steroids include obesity, hypertension, impaired wound healing, hyperglycemia, osteoporosis, and neuropsychosis.

As a result of these diffuse and nonspecific side effects, many centers have investigated the use of steroid-sparing or steroid avoidance protocols.^{38–40} In these studies, early withdrawal of steroids and steroid-free regimens were associated with an increase in biopsy-proven rejection but also demonstrated no significant differences in graft survival up to 5 years. Long-term (> 5 years) outcomes of steroid withdrawal protocols in kidney transplantation remain unknown. Many of these studies noted an improvement in other steroid-associated side effects, including cardiovascular risk factors, lipid profile, and weight gain, in the regimens using reduced steroids.

Costimulatory blockade Limitations to current immunosuppressive regimens include the lack of antigen specificity and the indiscriminate nature of global immunosuppression leading to opportunistic infection and the development of PTLTD. In addition, CNIs may contribute to diminished long-term allograft survival through direct nephrotoxicity and the development of chronic allograft nephropathy. Additional adverse effects associated with CNIs include hypertension, diabetes, and dyslipidemia. Costimulatory blockers have been investigated as novel therapeutic agents designed to avoid the chronic toxicities associated with CNIs and improve long-term allograft survival. Belatacept, a human fusion protein that combines a modified extracellular portion of cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) with the constant region fragment (Fc) of human IgG1, has been evaluated in phase II and phase III studies of kidney transplantation. In these trials, recipients who received belatacept versus cyclosporine had comparable patient and graft survivals at 12 months. However, the belatacept group had a higher incidence and grade of early acute rejection episodes and a higher rate of PTLTDs.^{41,42} Future questions to be answered include whether the higher rates of more severe rejection in the belatacept group will lead to a lower long-term graft survival with longer follow-up.

Treatment of rejection The approach to the management of allograft rejection depends on the type of rejection, the severity, and whether the episode represents a first occurrence or refractory rejection. In each case, the severity of rejection is best demonstrated by core-needle biopsy and histopathologic analysis. C4d staining and correlative DSAs are useful to evaluate for AMR. A stepwise approach to ruling out the other causes of rising creatinine in a kidney transplant recipient or other signs and symptoms suspicious for allograft rejection should be undertaken concurrently [see Figure 9]. Diagnostic tests to confirm or rule out these confounding causes should be undertaken, if indicated, before committing to additional immunosuppression.

In cases involving a first occurrence of rejection or mild acute cell-mediated rejection, pulse steroids in the form of intravenous methylprednisolone for 3 to 5 days are effective in reversing the majority of these episodes. When the rejection is severe or involves vasculopathy (Banff grade IIB or greater), or when the rejection episode is refractory to pulse steroids, treatment with rabbit antithymocyte globulin

(thymoglobulin) is indicated. Severe rejections may also benefit from increasing the drug levels of CNi temporarily to provide additional immunosuppression.

Therapeutic options in the patient with documented AMR include plasmapheresis alone, plasmapheresis with administration of IVIg, and plasmapheresis, IVIg, and rituximab. In cases where antibody levels are significantly high, the addition of rituximab may help lower the burden of antibody and ameliorate graft injury. However, the definitive benefits with the addition of rituximab in these patients remain unknown. In select cases, use of bortezomib (Velcade), a proteasomal inhibitor, may help reduce DSAs and help treat AMR in kidney transplant recipients.⁴³ It is important to remember that AMR may trigger a cascade of graft injury that can result in episodes of cellular rejection and that appropriate monitoring is required after treatment.

Summary

The clinical management of transplant recipients is based on the complex immunologic interactions between the donor organ and recipient outlined in the first part of this discussion. The innate immune system is the first line of defense,

with APC-derived TLRs engaging DAMPs and triggering the subsequent adaptive immune response. Optimal matching of a donor-recipient pair depends on precise HLA typing and accurate assessment of the immunologic risk in the recipient by evaluating preformed donor-specific antibodies. Cross-matching by flow cytometry and assessment of alloantibodies through solid-phase assays such as X-Map have become the standard of care. Carefully designed desensitization protocols have been used to limit the deleterious effects of alloantibodies and are used to supplement other creative approaches, such as kidney registries that match sensitized patients, to overcome the immunologic barrier. Treatment of allograft rejection requires a thorough understanding of the immunologic basis for allograft injury and currently involves histopathologic and immunohistochemical analysis of biopsied tissue. A variety of established agents form the mainstay of maintenance immunosuppression, but a host of novel agents are being developed that may play a role in selectively targeting alloimmunity without compromising host defense against pathogens.

13 SURGICAL CONSIDERATIONS IN SOLID-ORGAN TRANSPLANT RECIPIENTS

Pasithorn A. Suwanabol, MD, and Joshua D. Mezrich, MD

In 2008, over 27,000 patients received solid-organ transplants in the United States alone.¹ Advances in the management and the surgical techniques of solid-organ transplantation have led to a growing number of patients living long term with transplanted organs. In fact, the 5-year survival of living donor renal transplant and liver transplant has been reported at 91% and 79%, respectively.¹ As a result, general surgeons have a greater likelihood of encountering a posttransplant patient now than ever before.

Despite commonly held concerns, a large number of studies have demonstrated that immunosuppression is not a contradiction to surgery and good outcomes can be expected in the majority of patients.²⁻⁷ Additionally, abdominal surgery in transplanted patients is not infrequent, with reports of up to 10% of renal transplant patients experiencing a severe gastrointestinal (GI) complication within 10 years⁸ and 24% of liver transplant patients having another surgical procedure within 10 years.⁹

The extensive medication list of transplant recipients frequently seems complicated to caregivers with limited experience, often causing hesitation in evaluating these patients as surgical candidates. Additionally, it can be a challenging task to determine whether the benefits of the procedure outweigh the risks in this special population of patients. In general, as long as the surgeon adheres to basic surgical principles with frequent reevaluation and a low threshold for operative intervention, the disease processes should be manageable, with good outcomes.

It should be emphasized that these patients often present with surgical diseases in a manner unlike their immunocompetent counterparts and need aggressive intervention to achieve cures. Additionally, an appreciation for the balance between preventing graft rejection and infection or malignancy is essential.

This chapter focuses on special considerations in the solid-organ abdominal transplant patient. The goal of this chapter is to provide information for the practicing surgeon who is not at a transplant center to help decide when to perform an intervention or operation, how to modify standard procedures, and when to consider transfer to a transplant center if possible. It cannot be stressed enough that surgical intervention in these patients ideally should be carried out by the original transplant team. However, because the unstable or noncompliant patient is a reality, knowledge of perioperative management of transplant patients is critical for all nontransplant providers.

Preoperative Considerations

Discharge from the hospital is often met with anxiety in both the recent transplant recipient and his or her family

members and can be minimized by assurance and education. The transplant patient should have been counseled in medications, including the doses, functions, side effects and potential drug interactions, and recognition of signs and symptoms of rejection and infection. Therefore, patient participation should not be underestimated.

An extensive and expensive workup is unnecessary for minor ambulatory surgery in this population as there is a small complication rate and a low risk of compromising graft function.⁹ The surgeon should remember that the workup should focus more on the indicated procedure rather than the patient's immune status.^{9,10} Nevertheless, a thorough preoperative evaluation and understanding of the special considerations in this population are necessary to reduce risk.¹¹ There is typically no need to change medications around a minor procedure, except in select cases [see Management of Immunosuppression during the Perioperative Period, below].

When planning a major surgical procedure, it is essential for the surgeon to have knowledge of the patient's graft function. This will aid the surgeon in optimizing perioperative management of fluid and electrolyte status, medications, blood pressure, and ventilation as well as anticipating immediate postoperative care.¹² Consideration of transplant patients undergoing major surgery should follow the algorithm shown in Figure 1. Patients should provide a thorough history of symptoms related to their graft. For example, renal transplant patients vary in their ability to concentrate urine, and to avoid further graft dysfunction, it is critical to provide adequate hydration and careful monitoring of serum electrolytes. Liver transplant recipients should be asked about jaundice, pruritus, change in the color of urine or stool, and fluid retention.

Renal transplant patients often have associated multiorgan disease as a result of their primary condition (i.e., diabetes mellitus, hypertension) and should be evaluated for symptoms of underlying disease on a physical examination. Liver transplant recipients should be evaluated for underlying liver dysfunction: asterixis, ascites, and edema. As with renal and liver transplant recipients, pancreas transplant recipients should have a thorough physical examination with particular attention to the abdomen.

In most cases, standard laboratory values are adequate. For instance, in renal transplant recipients, an assessment of creatinine, urine protein/creatinine ratio, and glomerular filtration rate (GFR) may suffice. In liver transplant patients, assessment of coagulation and liver function tests (LFTs) may be adequate. In general, bilirubin and synthetic function becomes normal within 3 months following transplantation, and trends in LFTs should be monitored for abnormalities. Pancreas transplant recipients should have serum amylase and lipase, urine amylase (for bladder-drained transplants), and glucose levels monitored. Additionally, as the nutritional

Financial disclosure information is located at the end of this chapter before the references.

Figure 1 Algorithm for transplant patients who may need surgical management. CBC = complete blood count; GFR = glomerular filtration rate.

status of any patient is critical to decrease the risk of infection and improve wound healing, it is especially important in this particular patient population.^{9,11–15} Whenever possible, appropriate specialists (i.e., nephrologists, hepatologists) should follow the patient in the perioperative period.

As in any surgical procedure, it is essential to know the patient's anatomy and examine previous operative notes if at all possible [see Table 1 for a summary of common locations

and procedures for each transplant]. This will allow consideration of altered anatomy that can lead to unexpected complications. For instance, in patients who have had kidney transplants, the location of the organ, particularly the ureter, is crucial to avoid injury. A previously transplanted ureter looks remarkably like an adhesion even to the trained eye, and many have been divided during uncomplicated lysis of adhesions. This is particularly likely if the kidney was placed through a midline incision and the surgeon does not know on which side the graft was placed.

In patients who have undergone a pancreas transplant, one must consider if a Roux-en-Y reconstruction for drainage of the duodenum was used (or if the pancreas was bladder drained, although this is far less common in recently transplanted pancreata) or if the vein drains via the superior mesenteric vein or the iliac vein in the recipient. Likewise for the liver, knowledge of any vascular reconstructions is critical.

Diagnostic and Radiologic Considerations

Although the physical examination is critical in the evaluation of any surgical patient, caution must be exercised in the transplant patient, particularly those patients who have been on immunosuppression for many years. It is not unheard of to explore a patient with a near-normal examination and be surprised to find an abdomen full of succus. For this reason, we are aggressive in obtaining abdominal imaging in the majority of transplant patients who are being evaluated for an intra-abdominal process.

Consideration should be made for diagnostic sampling of any fluid collections or free intra-abdominal fluid that is not expected to rule out surgical causes. Fluid is typically sent for Gram stain and culture, bilirubin, amylase, creatinine, and any other biochemical marker that is relevant to the situation. In general, it is acceptable to follow patients conservatively if that is the judgment of the caregiver, but frequent reassessments are necessary. If the patient does not improve quickly, consideration should be made for aggressive intervention or at least reimaging.

When it comes to choosing radiologic imaging, similar algorithms should be used, as in the nontransplant patient. As in their immunocompetent counterparts, immunocompromised patients may undergo ultrasonography to evaluate the biliary tree, kidneys or ureters, and the female reproductive organs. Computed tomography (CT) is the best tool for assessment of intra-abdominal fluid.¹⁶

Transplanted patients being evaluated for trauma should be assessed as any other trauma patient.^{10,17} Kidney transplant patients often have creatinine levels that run higher than those in the nontransplant patient, with values in the range of 2 mg/dL or above even with stable function. Appropriate hydration decreases the risk of nephrotoxicity similar to that of nontransplant patients,¹⁷ and standard bicarbonate protocols are similarly helpful. If CT is warranted for safe management of the trauma, it should be conducted. It may be useful to hold the calcineurin inhibitor (cyclosporine or tacrolimus) for a few days following the contrast load as these drugs are nephrotoxic. Holding a calcineurin inhibitor for a few days in the setting of a trauma

Table 1 Anatomic and Diagnostic Details of Abdominal Organ Transplants

<i>Solid-Organ Transplantation</i>	<i>Anatomic Location and Variability</i>	<i>Anastomoses</i>	<i>Relevant Laboratory Studies</i>	<i>Common Medical Sequelae, Presentation, and Diagnostic Tests</i>
Liver	Bilateral subcostal incisions with midline extension. Liver is placed in an orthotopic position.	In a piggyback technique, the suprahepatic vena cava of the donor is anastomosed to the orifice of the hepatic veins of the recipient. In caval replacement, recipient cava is removed and the suprahepatic and the infrahepatic cava of the donor are anastomosed end to end. End-to-end arterial anastomosis using aortic Carrel patch of donor celiac artery and branch patch of recipient artery at right and left bifurcation. Variations are possible. Also consider aortic jump graft from supraceliac or infrarenal aorta to donor celiac. Biliary anastomosis via duct to duct or hepaticojejunostomy with a Roux-en-Y reconstruction depending on underlying biliary pathology.	PT/PTT, AST/ALT for liver function; bilirubin, GGT, alkaline phosphatase for biliary stricture or cholangitis	1. Acute rejection: elevated LFTs; biopsy advised 2. Chronic rejection: elevated LFTs, liver dysfunction, ascites; biopsy advised 3. Recurrent disease (HCV most common): elevated LFTs, liver dysfunction, ascites, portal hypertension; biopsy and HCV PCR advised 4. Biliary pathology (i.e., stricture, cholangitis, biloma); assess arterial patency with ultrasonography or CTA; ERCP for direct assessment; if Roux-en-Y hepaticojejunostomy, MRCP and/or PTC
Pancreas	Midline incision used most frequently. Rarely, two lateral incisions for simultaneous pancreas-kidney transplantation. Usually, pancreas is on right side, placed head (duodenum) up posterior to the right colon.	Donor iliac bifurcation graft (that is reconstructed to the SMA and splenic artery of the donor pancreas) anastomosed end to side to recipient common iliac artery. Donor portal vein to recipient vena cava or common iliac artery. Some centers use superior mesenteric vein tunneled retrocolic with a jump graft. Duodenum usually enterically drained to jejunum. Occasionally, bladder is drained, in which case will sit head (duodenum) down.	Amylase, lipase	1. Allograft pancreatitis: elevated amylase/lipase; CT 2. Fistula and abscess: fevers, sepsis, pain; CT 3. Urologic complications in bladder-drained pancreas: urethritis, hematuria, frequency, metabolic acidosis; cystoscopy
Kidney	Retroperitoneal entry through oblique incision (Gibson) above the inguinal ligament	Renal artery(s) end to side to common or external iliac artery. Renal vein to common or external iliac vein. Ureter plugged directly into bladder. Occasionally, ureter sewn to native ureter (ureteroureterostomy).	Creatinine, urine protein/creatinine ratio, GFR	1. Acute cellular rejection: elevated creatinine, leg swelling and fluid overload; biopsy advised 2. Chronic allograft nephropathy (i.e., interstitial fibrosis/tubular atrophy): elevated creatinine, fluid overload; biopsy advised 3. Hydronephrosis: elevated creatinine, pain; ultrasonography or CT, nephrostography 4. UTI: fevers, dysuria, dehydration, elevated creatinine; UA/culture 5. Recurrent disease: elevated creatinine; biopsy advised

ALT = alanine aminotransferase; AST = aspartate aminotransferase; CT = computed tomography; CTA = computed tomographic angiography; ERCP = endoscopic retrograde cholangiopancreatography; GFR = glomerular filtration rate; GGT = γ -glutamyl transferase; HCV = hepatitis C virus; LFT = liver function test; MRCP = magnetic resonance cholangiopancreatography; PCR = polymerase chain reaction; PT = prothrombin time; PTC = percutaneous transhepatic cholangiography; PTT = partial thromboplastin time; SMA = superior mesenteric artery; UA = urinalysis; UTI = urinary tract infection.

typically is safe. Depending on the patient, extra steroids (such as the equivalent of 10 to 30 mg of prednisone per day) can be considered during this period, although, again, if use is limited to a few days, it is probably unnecessary. Ideally, this would be done in consultation with an appropriate specialist or transplant center.

Intraoperative Considerations

Since the introduction of minimally invasive techniques, transplant surgeons have been active participants in its use, from ultrasound-guided biopsy to laparoscopic donor nephrectomy. As in immunocompetent patients, the use of minimally invasive techniques in immunocompromised patients is safe and provides the same benefits, such as decreased hospital stay and narcotic use, as well as comparable or even improved complication rates.^{18–21} A skilled laparoscopic surgeon should always offer the immunocompromised patient the laparoscopic alternative when available and feasible.

During any reoperation following a kidney transplantation, one should always be thinking of the ureter. If one does come across and divide the ureter unexpectedly, the most likely repair will be a ureteroureterostomy, using the patient's native ureter and sewing it end to end over a stent after spatulation. Most commonly, this does not require a native nephrectomy even if the patient's native kidney makes urine, although, in occasional cases, hydronephrosis can follow, requiring a native nephrectomy at a later time point.

As a general rule, similar principles of surgical technique should hold with the transplant patient. Additionally, any procedure that is reasonable in the nontransplant patient can be used in the transplant patient. We do caution the practitioner who has not had a lot of experience with transplant patients that the long-term immunosuppressed patient in particular certainly has an increased risk of poor healing or wound or anastomotic dehiscence. Moreover, the patient will not always show the signs of sepsis that are commonly noted when this happens. Note that there is no real definition of "long term," and this is an anecdotal observation. In general, those patients who have been immunosuppressed for a decade or more seem to be at higher risk for complications related to healing. Therefore, any transplant patient who simply does not progress and heal in a fashion that seems reasonable should be considered for a complication, and aggressive radiologic assessment is recommended.

Antibiotics and Pain Medicine in the Perioperative Period

It is well established that immunocompromised patients encounter many more infections than their immunocompetent counterparts, in particular rare fungal, bacterial, and viral infections.^{10,15,22–28} Fifty to 70% of transplant patients have at least one episode of bacterial infection, and 30 to 60% have at least one serious viral infection.^{10,29} In general, posttransplant patients have a predictable infectious course: within the first posttransplant month, infections are comparable to those of their immunocompetent counterparts and are usually bacterial in nature; in months 1 through 6, patients are at risk for opportunistic infections, including

Pneumocystis carinii, *Listeria monocytogenes*, and *Aspergillus* species; more than 6 months posttransplantation, two thirds of patients suffering from an infection will develop a community-acquired respiratory virus, whereas the remainder will develop chronic viral infections (such as hepatitis B and C viruses). A group at particular risk are those who received excessive amounts of immunosuppression as a result of early rejection or delayed graft function, causing the greatest risk of infection from opportunistic pathogens such as *Cryptococcus neoformans*, *P. carinii*, and *L. monocytogenes*.^{30,31} Other viruses that are quite well known to transplant physicians are cytomegalovirus and BK virus, which can cause nonspecific symptoms such as fevers or diarrhea but can also cause graft dysfunction or loss of a graft. Certainly, any transplant patient who is suffering from more than an easily diagnosable and treatable urinary tract infection, pneumonia, or line infection should undergo workup for these pathogens, and consideration should be given to transferring to a transplant center.

There is no evidence of prolonged perioperative antibiotic (greater than 24 hours) use despite the widespread use of prophylactic antibiotics in a patient's medication regimen. This is attributable to an increased risk of viral and fungal infections in addition to superinfection with resistant bacteria and/or *Clostridium difficile*.^{11,32} Surgical prophylaxis should include therapies against skin flora such as staphylococci and streptococci and, in renal transplant patients, the inclusion of therapies against urine species such as *Escherichia coli*, *Klebsiella*, and *Proteus*. In suspected infection, empirical therapy should be guided by the suspected anatomic site and organism, previous antibiotic therapy, renal and hepatic function, and immunosuppression status. Continued therapy after identification of an organism should be as specific as possible with consideration of renal and hepatic function.

Postoperatively, consideration of hepatic and renal function is necessary when choosing medications such as narcotics and antihypertensives. For example, in patients with suboptimal liver function, morphine, meperidine, or propoxyphene for pain management and clonidine or nifedipine for hypertension are preferred.⁹

Management of Immunosuppression during the Perioperative Period

Immunosuppression in the solid-organ transplant patient often includes several agents with different mechanisms to use lower doses and decrease potential toxicity.³¹ Additionally, in the late postoperative period (2 to 6 months), immunosuppression is usually decreased as the allograft is typically functioning well and rates of rejection are highest in the first 6 months, with decreasing incidence thereafter. When considering elective procedures, it may make sense to delay them for up to 6 months after transplantation or at least the point where they are down to their baseline maintenance immunosuppression. This, of course, has to be balanced with the urgency or risk of delaying the surgical procedure.

Immunosuppression is associated with an increased susceptibility to infection and poor wound healing.^{10,33} However, a balance between preventing graft rejection

and anticipating the patient's response to surgical stress must be appreciated. If the procedure is unable to be performed by the original transplant team, the surgeon should not hesitate to consult a transplant service for immunosuppressive guidelines.⁹

Although historically there has been concern over a immunocompromised patient's ability to undergo surgical procedure, a number of studies demonstrate that these patients are able to undergo a variety of procedures with complication rates similar to those of their immunocompetent counterparts^{34–37} and without an increased risk of wound healing problems.^{9,38,39} In general, immunosuppression is not altered during the perioperative period unless the patient is demonstrating significant infection or sepsis. It should be given at the same schedule and dose as the patient's home regimen.⁹ If the patient is unable to take anything orally, azathioprine and mycophenolate mofetil (MMF) can be safely withheld for 2 to 3 days. Intravenous cyclosporine can be used at one third the total daily oral dose over 4 to 8 hours. Until the patient is able to tolerate immunosuppression by mouth, immunosuppression levels should be checked daily, with the goal of having no variation from baseline greater than 25%.⁹ There are some exceptions to this, however. Most transplant surgeons would suggest discontinuing sirolimus and changing to a calcineurin inhibitor as sirolimus has been known to impair wound healing.^{11,40}

In our own practice [see Table 2 for a summary of the medicines and recommended adjustments], for minor procedures, we do not recommend any change in immunosuppression. Patients can take their medicines on the morning of surgery and resume them that night or the next morning, depending on how they are feeling. It is important that patients stay well hydrated perioperatively as the calcineurin inhibitors are nephrotoxic, and this is compounded by a prerenal state. Therefore, we are more aggressive about admitting patients for a day or two after surgery or at least following their laboratory results (organ specific labs are drawn as outpatients at their local clinic/hospital, and results are faxed to the transplant unit) as outpatients and seeing them more frequently if admission is not necessary or feasible. For more extensive procedures, particularly those that will require patients to be nihil per os (NPO) for a period of time, we typically hold their calcineurin inhibitor and put them on the equivalent of 20 to 30 mg of intravenous prednisone per day (we typically use dexamethasone, 2 mg every 8 to 12 hours IV, until they can return to their home dose). This obviously depends on what organ they have received, how recent the transplantation was, and what their rejection history is.

If the patient is well clinically and at high risk for rejection (young, recent transplant, previous episodes of rejection, African American, kidney transplant recipient), then consideration can be made for using intravenous cyclosporine if the patient is on that medication or sublingual tacrolimus (typically half the dose of oral). If this is done, levels should be followed daily until they return to the patient's normal oral dose and baseline levels have been achieved. If at all possible, we do recommend at least discussing the plan with the transplant physician prior to the surgery and, ideally, having his or her input in the perioperative period. If the

patient is on MMF, we usually continue this drug intravenously. A well-known side effect of this drug is diarrhea or other GI symptoms, so if the procedure is a major GI operation, it may be necessary to hold this until bowel function normalizes.

We would offer caution considering any operation on a patient who is on sirolimus. This drug has a dramatic effect on wound healing, and, ideally, we stop this drug 2 months before an elective procedure, substituting a calcineurin inhibitor if possible. We would prefer that the patient remain off this drug at least 2 months after the procedure, assuming that the wound has healed well. For those patients who have more urgent procedures, we would at least recommend that sirolimus is held postoperatively for 2 months or more, again substituting alternative agents. All of these decisions should be made in concert with the transplant physicians.

A common concern for nontransplant practitioners is the use of stress-dose steroids in the transplant patient population. Although patients on immunosuppressive medications may have abnormalities of the pituitary-adrenal axis, there is no evidence to support the use of increased steroids in the perioperative period.^{9,33,41} In fact, the use of high-dose steroids promotes poor wound healing, causing both slower healing and decreased strength of the wound.^{9,10} This effect has been offset by the administration of vitamin A supplementation.^{10,42} Stress-dose steroids may be indicated when a patient demonstrates adrenocortical insufficiency, as evidenced by clinical symptoms of weakness, nausea, vomiting, and fever.² To reiterate, the use of stress-dose steroids is not supported or advocated prophylactically in any procedure. It may be reasonable to consider stress-dose steroids in the septic patient or those patients undergoing major surgery with unexplained hypotension or other signs of adrenocortical insufficiency but otherwise may not be necessary.

Complications

Fortunately, the complication rate for elective procedures in this patient population is similar to that of immunocompetent patients. However, emergent procedures are associated with increased morbidity and length of hospital stay.⁹ Most authors would advocate an aggressive approach to this group of patients, with surgical revision early if possible.¹¹ It is crucial to remember that transplant patients can have very subtle findings even with major postsurgical complications or infections. As a general rule, any patient who is not progressing as expected should undergo aggressive workup for complications, including liberal use of imaging and diagnostic tapping or reoperation in response to unexpected fluid collections. All fevers should be worked up aggressively either for preexisting infections or peri- or postsurgically acquired infections.

Follow-up

Follow-up for the immunocompromised patient after surgery should proceed in the same manner as performed in an immunocompetent patient. Generally, patients are seen 2 weeks after discharge depending on the hospital course and condition of the wound. Patients are continued on their

Table 2 Considerations for Common Immunosuppressive Agents

Common Immunosuppressive Agent	Mechanism of Action	Therapeutic Levels	Perioperative Management	Sepsis Management	Relevant Known Impact on Surgery	Common Side Effects	Main Advantages
Steroids	Inhibition of macrophage cytokine production; inhibition of IL-1, IL-6, TNF secretion; suppress T cell cytokine production	Not measured	Stress-dose steroids (10–30 mg prednisone/day) is appropriate in a trauma setting, sepsis, or demonstration of adrenocortical insufficiency. No data supporting use in elective cases.	Stress-dose steroids may be considered	Poor wound healing, increased risk of infection. In general, can proceed with surgery.	HTN, weight gain, peptic ulcer disease, GI bleeding, personality changes, cataract formation, hyperglycemia, increased susceptibility to pyogenic and opportunistic infection	Cheap, wide-spread use
Calcineurin inhibitors (cyclosporine, tacrolimus)	Cyclosporine: inhibition of helper T cell cytokine production, particularly IL-2; impairs maturation and propagation of thymic CD4 ⁺ and CD8 ⁺ T cells Tacrolimus: inhibits T cell activation, blocks induction of IL-2; blocks cytokine production; indirectly blocks T cell proliferation	Cyclosporine trough levels: kidney transplant < 6 months—aim for 250–350 µg/L; > 6 months—aim for 100–200 µg/L Tacrolimus trough: typically 8–10 ng/mL	Hold for 2–3 days following radiographic contrast load; if NPO, calcineurin inhibitors are held and patients placed on 20–30 mg of prednisone/day IV; high-risk patients may have oral calcineurin inhibitors held and be placed on IV cyclosporine or sublingual tacrolimus	Consider holding and maintain only on prednisone	Very narrow therapeutic window requires great care in prescribing medications also metabolized by the P-450 system	Cyclosporine and tacrolimus: nephrotoxic posttransplantation diabetes, HTN, headache, tremors	Cyclosporine: no myelosuppression Tacrolimus: more potent, no hirsutism or gum hypertrophy
Mycophenolate mofetil (MMF)	Prevent differentiation and division of immunocompetent lymphocytes	Typically levels not measured, although MPA levels are available	If NPO, may be changed to IV or safely held for 2–3 days if major GI procedure	Consider holding and using steroids alone		GI upset/diarrhea	Potent
Azathioprine	Prevent differentiation and division of immunocompetent lymphocytes		May be held for 2–3 days if patient is NPO	Consider holding and using steroids alone		Bone marrow suppression, liver toxicity, skin cancers	Not used as much as MMF
Sirolimus	Inhibition of IL-2 signaling to cell nucleus		If major procedure, hold for 2 months previously and substituted with calcineurin inhibitor; if emergent, hold for at least 2 months postoperatively and substituted with alternative agents	Consider holding and using steroids alone	Delayed wound healing, which can be severe; increased incidence of lymphocele formation	Increased triglycerides; decreased platelets; decreased hemoglobin; increased proteinuria	Decreased nephrotoxicity

GI = gastrointestinal; HTN = hypertension; IL = interleukin; IV = intravenous; MPA = mycophenolic acid; NPO = nihil per os; TNF = tumor necrosis factor.

home immunosuppression, and, as stated previously, unless there is a specific reason, antibiotics are not extended. In our practice, wounds are left covered for 48 hours after surgery, and staples are typically removed 3 weeks after surgery to account for slow healing. Obviously, clinical assessment of wounds may override these recommendations. Levels of calcineurin agents (cyclosporine or tacrolimus) should be followed closely for a few weeks after surgery until the preoperative therapeutic range is achieved. It is common for people to have either high or low levels after surgery, particularly until bowel function has returned to normal. There is a risk that rejection can occur in the postoperative period if levels are too low, and if a patient is having difficulty getting the level up quickly, extra steroids (or another agent) may be required for a few weeks while the level is returning to baseline.

When to Consider Transfer to a Transplant Center

The decision on when to transfer a patient to a transplant center will depend on many factors, including geography, comfort level of the caregivers, desires of the patient, size of the procedure, organ that was transplanted, and postoperative course. Many procedures can be conducted safely on transplant patients without specialized care from a transplant center. However, some patients are reluctant to have anyone other than their transplant physicians treat them once they have received a transplant, and some transplant physicians likewise will agree with that. Ideally, a discussion will take place with both the patient and the transplant physician prior to the procedure to make a plan. If a surgeon is comfortable performing a procedure or operation, the same attention to good technique will apply to these patients. All postoperative complaints or findings should be evaluated very carefully, and if at any point a patient is not progressing appropriately, contact should be made with the transplant center with consideration of transfer. A transplant physician or specialist with some comfort in transplant medications or infections should be consulted if at all possible. Discussions with transplant physicians or pharmacists regarding medications and any alterations in them should be conducted daily if possible.

Special Considerations

ACUTE APPENDICITIS

Although the occurrence of acute appendicitis in the general population is widespread, its frequency in transplant recipients is quite rare, with a reported rate of 0.2% in liver, heart, kidney, and pancreas recipients.⁴³⁻⁴⁶ Nevertheless, given the rising number of transplant recipients, knowledge of the management of this disease in this patient population is important.

In the past, appendectomies in conjunction with a pancreas transplant were routine to prevent misdiagnosis of transplant pancreatitis. However, the low incidence and reliability of modern imaging in visualizing acute appendicitis no longer make this current practice at most institutions.

Ultimately, transplant recipients found to have acute appendicitis should be managed similarly to nontransplant

patients with the use of laparoscopy based on surgeon preference. As with any intra-abdominal pathology in a transplant recipient, clinical signs can be subtle. Therefore, imaging is crucial in securing the diagnosis.

Our institution is aggressive about proceeding with operative management in patients with acute appendicitis. If management of nontransplant patients includes consideration of percutaneous drain placement and interval appendectomy in perforated and walled-off appendicitis, the same can be considered in the transplant patient. These patients do require close monitoring with serial examinations and reimaging. It cannot be stressed enough that the signs and symptoms of progression can be subtle. A low threshold to abandon conservative management in favor of operative intervention should be considered in patients who do not rapidly improve.

SMALL BOWEL OBSTRUCTION

As a result of medical immunosuppression, transplant recipients rarely develop extensive adhesions causing small bowel obstruction. However, it has been hypothesized that transplant and nontransplant patients develop small bowel obstruction similarly, mainly the formation of adhesions following intra-abdominal surgery. Additionally, there have been reports of small bowel obstruction secondary to internal hernias in pancreas transplant recipients.^{47,48} The increased risk of malignancy in this patient population should also make the surgeon suspicious of a malignant etiology.

As in nontransplant patients, obstruction can be fatal and should be managed similarly. Conservative management with nasogastric tube decompression, hydration, and close monitoring is appropriate. If the patient does not improve quickly, operative management is imperative.

PEPTIC ULCER DISEASE

Prior to the advent of histamine₂ blockers, mortality from peptic ulcer disease in this patient population was as high as 40%^{49,50} and was even reported to be approximately 4% only a few years ago.⁵¹ The cause of peptic ulcer disease in this patient population is multifactorial. There have been reports of up to 62% of living donor liver recipients^{52,53} and approximately 30% of renal transplant recipients with *Helicobacter pylori* colonization.^{8,51,53,54} Additionally, high-dose steroids used to treat rejection have been found to be ulcerogenic,⁵⁵ and MMF has been found to cause ulcer perforation or bleeding in 3 to 8% of patients within 6 months.⁵⁶

Transplant patients are typically placed on prophylactic medications in the perioperative period to prevent the development of peptic ulcer disease. Fortunately, in our practice, we have rarely had to operate on this as in our nontransplant patient population. Surgical management, when necessary, should be no different than in the nonimmunosuppressed patient.

BILIARY TRACT PATHOLOGY

Cyclosporine therapy has been associated with biliary calculous disease and primary choledocholithiasis.¹⁰ However, studies have demonstrated the safety of cholecystectomy

following transplantation despite previously held beliefs regarding immunosuppression and surgery.⁴⁹

Biliary tract pathology is common in liver transplant recipients, with an incidence of 10 to 30% and the majority seen within the first 6 months posttransplantation.⁵⁷ Most commonly, anastomatic stricture of the bile duct following duct to duct reconstruction occurs, resulting in patients who present with symptoms of cholangitis. Elevated bilirubin, fevers, and sepsis warrant urgent endoscopic cholangiopancreatography and broad-spectrum antibiotics. Because of the tenuous condition of these patients, transfer to a transplant center is highly recommended.

DIVERTICULITIS

Diverticulitis in the transplant patient population is higher (1% versus 0.02%)⁵⁸ and more aggressive⁵⁹ than in the general population. In a study comparing immunosuppressed and immunocompetent patients with acute diverticulitis, immunosuppressed patients were found to have an increased risk of free perforation (43% versus 14%) and postoperative mortality (39% versus 2%).⁶⁰ Therefore, patients are typically offered surgical intervention following a single episode of uncomplicated diverticulitis if it is safe and once the acute episode resolves.⁶¹ Although there is a paucity of data to support this in the literature, the risk of complications from recurrent episodes and difficulty in diagnosing these patients until they progress to a later stage of disease may be an incentive to intervene earlier than in nontransplant patients.

Acute episodes of diverticulitis are managed conservatively with broad-spectrum antibiotics and percutaneous drain placement. However, frequent reassessment and reimaging are critical. Interval surgical intervention should always be considered if the patient does not progress. In our practice, we have been cautious in performing a primary anastomosis in acute complicated diverticulitis in the sigmoid region, particularly in patients on long-term immunosuppression. We favor reestablishing continuity 3 to 6 months later. Of note, great caution should be taken with patients on sirolimus at the time of presentation. These patients are notoriously poor at healing, and strong consideration should be given for diverting these patients in the acute setting.

MALIGNANCY

Clinicians should have an appreciation for the increased risk of cancer associated with immunosuppression. Although the exact risk remains controversial, the incidence of malignancy in transplant recipients is increasing, and there are estimates that after 10 years of chronic immunosuppression, the incidence of malignancy is 20%.⁶² The risk of malignancy can vary based on the medication and type of cancer and is believed to be closely associated with overall exposure to immunosuppression.⁶²

In general, solid-organ tumors of the GI tract have an approximately 1.25 to 5 times and lymphomas a 10 times greater incidence in transplant patients.⁶³ In solid-organ transplant recipients, nonmelanotic skin cancers are extremely common,^{64,65} with transplant patients at a 65-fold increased risk of developing squamous cell carcinoma.⁶⁶ For this reason, all patients should be followed by a dermatologist.

As with nontransplant patients, transplant patients with solid tumors should be followed under the same oncologic principles. Multidisciplinary teams including transplant physicians, oncologists, and surgeons are necessary for the care of these patients.

A special note should be made regarding posttransplantation lymphoproliferative disorder (PTLD). PTLD is the second most common malignancy seen in renal transplant patients⁶⁷ and the most common malignancy in liver transplant patients.⁶⁸ It can have variable presentations, including abdominal pain, small bowel obstruction, weight loss, and GI bleed. The presence of masses on a CT scan is suggestive of PTLD, with 25% involving the small bowel and 6% involving the colon.⁶⁹ PTLD may cause bowel obstruction, necessitating emergent surgery. Interestingly, simply reducing immunosuppression can sometimes cause eradication of disease. Additionally, as the majority of cases are B cell in nature and associated with Epstein-Barr virus, B cell-directed therapies such as anti-cd20 antibody rituximab, may eliminate the disease. Consequently, patients with PTLD should be managed at a transplant center where graft loss or mortality can be minimized by the modification of immunosuppression and other therapies.

GASTROINTESTINAL PROBLEMS

Immunosuppressants often have GI effects that modify symptoms and therefore the presentation of GI diseases.⁴⁹ It is quite common for transplant patients to develop diarrhea, sometimes severe episodes. This can sometimes be related to transplant medications, and a careful drug history should be the initial step in evaluating a transplant patient with diarrhea. For example, up to 50% of patients on MMF develop GI complaints.⁷⁰ Ruling out other causes, particularly infections, is important and can be challenging. Infectious processes often seen in the transplant population include *C. difficile* superinfection, cytomegalovirus colitis, more common GI viruses, and opportunistic infections. The initial workup should be no different from that for the nontransplant patient but may ultimately require colonoscopy and biopsy to rule out the above.

Summary

General surgeons can certainly have some level of comfort with the knowledge that with careful attention to medications and symptoms, general principles will hold true with transplant patients. Minor procedures can usually be conducted without much modification, and more major procedures may require some adjustment of medication regimen. The most important point is to watch these patients closely as their physical examination, including vital signs and laboratory studies, can be misleading, and frequent reassessment with imaging may be necessary. If a patient does not proceed along the expected recovery, attention must be given to a possible complication. Most transplant centers have a program for following up with their patients and a contact to call for questions about their care and organ function. It is always recommended to communicate with a program. Consideration for transfer to a transplant center may be appropriate in complicated cases or in the setting of complications.

21 MINIMALLY INVASIVE SURGERY: EQUIPMENT AND TROUBLESHOOTING

Luke M. Funk, MD, MPH, and Jacob A. Greenberg, MD, EdM

The field of minimally invasive surgery has evolved rapidly since the first laparoscopic appendectomies and cholecystectomies were performed nearly 30 years ago.¹ Minimally invasive approaches are now widely used for gastrointestinal resection, hernia repair, antireflux surgery, bariatric surgery, and solid-organ surgery, such as hepatic, pancreatic, adrenal, and renal resections. Although the techniques and equipment needed to access, expose, and dissect vary according to the type of operation and surgeon's preference, a basic set of equipment is essential for any laparoscopic procedure: laparoscope, camera, light source, signal processing unit, video monitor, insufflator and gas supply, trocars, and surgical instruments. Understanding how to use and troubleshoot this equipment is critical for any surgeon who performs minimally invasive surgery.

In this chapter, we review the essentials of basic laparoscopic equipment, including the mechanics of normally functioning equipment and the various types of laparoscopic trocars and instruments. Additionally, we discuss potential technical difficulties that surgeons may encounter while using laparoscopic equipment and instruments and provide suggestions for troubleshooting these problems.

Laparoscopic Equipment

LAPAROSCOPE AND CAMERA

The purpose of the laparoscope and camera unit is to transmit high-quality images from the surgical field to the signal processing unit, which relays the images to the video monitor. Traditional laparoscopes have two separate channels. One channel contains a series of glass rods (known as the Hopkins rod-lens system²) that transmit images from the surgical field to the eyepiece of the laparoscope. The second channel contains light fibers, which transmit light from an external source to the surgical field.

Laparoscopes may be straight or angled at the tip. Straight (0°) laparoscopes offer a view of whatever lies directly ahead of the laparoscope, whereas angled (e.g., 30° or 45°) scopes allow the surgeon to look around structures by rotating the scope [see Figure 1]. Typically, laparoscopes are either 5 or 10 mm in diameter and are usually 25 to 30 cm in length. Smaller diameter laparoscopes, such as 3 mm scopes, are also available, although they tend to be less durable [see Figure 2]. Longer laparoscopes (e.g., 40 to 45 cm) are also available and are frequently used in bariatric cases.

To transmit images from the laparoscope to the signal processing unit, a camera is attached to the eyepiece via a coupler [see Figure 3]. First-generation cameras developed in

Figure 1 Angled (upper image) versus straight (lower image) laparoscope. Courtesy of KARL STORZ Endoscopy-America, Inc.

the 1980s used a “one-chip” system to convert colors into electrical charges and relay those images. Most current-generation laparoscopic cameras use “three-chip” charge-coupled device systems, which sense primary colors (red, blue, green) and convert these colors to electrical charges. This enhancement allows for a higher image resolution. In one study, three-chip cameras provided up to 800 lines of horizontal resolution compared with 640 lines for a one-chip camera.³ Interestingly, the clinical impact of this superior resolution is unclear. In a 1995 study, surgeons and nurses who were blinded to either a one-chip or a three-chip system actually preferred the one-chip system.⁴ The authors concluded that the enhanced resolution offered by three-chip imaging may not have been appreciable to the human eye. However, subsequent improvements in color detection and light sensitivity over the last 15 years have made three-chip systems the standard in many operating rooms. Modern high-definition three-chip systems can offer more than 1,000 lines of resolution.

Digital laparoscopes are also available. These devices combine the laparoscope and camera into one unit. Rather than using the traditional rod-lens system, they contain an image sensor at the distal end of the laparoscope that transmits images. One advantage of digital laparoscopes is that flexible-tipped scopes can be used to provide additional visibility compared with traditional straight or angled scopes, which are rigid cylinders [see Figure 4]. However, these systems may not be compatible with video systems that use the traditional rod-lens laparoscopes.

LIGHT SOURCE AND CABLE

One of the early limitations of laparoscopic surgery was the need to place the light source in the surgical field, often at the distal end of the laparoscope. As a result, images were relatively low quality, and intra-abdominal thermal burns were not uncommon. This changed in the 1950s with the development of the “cold light source,” which included the quartz light rod and, subsequently, fiberoptic technology.^{5,6} Light could now be generated by an external source and

Figure 4 Flexible-tipped laparoscope, which offers wider visibility of the surgical field. Courtesy of KARL STORZ Endoscopy-America, Inc.

transmitted to the surgical field through fiberoptic bundles. This provided clearer, brighter images and reduced the likelihood of thermal injuries.

Several types of light sources are used during minimally invasive procedures today. Halogen (150 watt), metal halide (50 to 270 watt), xenon (300 watt), and, more recently, light-emitting diodes (LEDs) are all high-intensity light sources capable of producing quality images on a video monitor. One of their main differences is their life span. Halogen and metal halide light sources typically last several hundred hours, whereas xenon bulbs may last up to 500 hours.

Despite their classic label as “cold light sources,” each of these light sources generates a substantial amount of heat. One study of three different xenon light sources found that temperatures near the outlet of the light source exceeded 1,000°F, whereas those near the tip of the fiberoptic cable approached 500°F. Temperatures at the tip of the laparoscope ranged from 140 to 212°F. Evidence of small bowel injury occurred after only 5 seconds of direct contact between the laparoscope and the bowel.⁷ In another study, charring of the surgical drapes occurred after 3 to 6 seconds of contact between the tip of the light cable and the surgical drapes.⁸ The surgeon must be cognizant of the risk of thermal burns from either the lighting equipment or the laparoscope.

LED light sources are a fairly recent addition to the laparoscopic armamentarium and are purported to have numerous advantages. They are more efficient than other light bulbs (they release more light per watt) and emit less heat than standard light sources. Additionally, their life spans are anywhere from 10 to 100 times longer than standard light sources. However, they are more costly than traditional light sources (e.g., xenon).

SIGNAL PROCESSING UNIT (CAMERA CONTROL UNIT)

Once the camera has processed the images from the surgical field, the images are transmitted to a signal processing unit. The purpose of the signal processing unit is to transmit the signal from the camera to a variety of end devices, including printers, recording devices, and, most importantly, the video monitor. Several analog output signal formats are commonly used by signal processing units, including composite, Y/C (super video), and RGB (red/green/blue) signals [see Figure 5]. Composite signals, which use a single pin connection, are typically lower quality than Y/C or RGB signals. RGB signals, which use three wires for color and one wire for synchronization, often offer the best image.⁹

Digital video interface (DVI) and serial digital interface (SDI) signals are the two most commonly used digital signal outputs. DVI signals are essentially a digital version of an RGB signal. One limitation of DVI is that the cable length cannot be longer than 15 feet because of signal degradation.⁹ On the other hand, SDI cable lengths can be much longer without causing significant signal degradation.

VIDEO MONITOR

Most traditional video monitors used in the operating room will accept input from three types of analog signals: composite, Y/C, and RGB. Older laparoscopic camera systems typically output either composite or super video signals, whereas many current-generation systems also generate RGB output, which often provides higher-resolution images. However, even with the use of RGB signals, the resolution provided by traditional cathode ray tube monitors is somewhat limited (typically 600 lines or less).¹⁰ For enhanced resolution, including high-definition formats, digital monitors that accept DVI and SDI digital signals may be used with high-definition video cameras. These flat-panel digital monitors, which are also capable of accepting analog signals, are often ceiling-mounted displays that are capable of providing more than 1,000 lines of resolution (nearly twice the resolution of a typical television image).¹⁰

INSUFFLATOR AND GAS SUPPLY

The creation of pneumoperitoneum is one of the essential steps of laparoscopic surgery because it distends the abdominal wall and significantly enhances visualization of intra-abdominal structures. One of the first physicians to insufflate

the abdomen was Dr. George Kelling, a German surgeon who is also credited with performing the first laparoscopic procedure in 1901.¹ Interestingly, improved intra-abdominal visualization was not one of his primary goals. Rather, he wanted to arrest gastrointestinal bleeding by injecting large amounts of air into the peritoneal cavity to create extremely high intra-abdominal pressures (50 to 100 mm Hg).¹¹ Shortly thereafter, a Swedish internist named Hans Christian Jacobaeus used a trocar with a bulb and a one-way valve to manually insufflate air into the abdomen. He referred to this new procedure as “laparoscopy.” His first 17 human cases were diagnostic procedures in patients with ascites. Unlike Kelling, Jacobaeus realized that laparoscopy had tremendous potential and published several articles in the European literature.¹¹ Manual insufflation would remain the standard technique for the creation of pneumoperitoneum for another five decades.

In the 1960s, Dr. Kurt Semm, a German gynecologist who performed the first laparoscopic appendectomy in 1983, developed an automatic insufflator that monitored the pressure of pneumoperitoneum.¹² This device not only provided surgeons with a reliable estimate of intra-abdominal pressure; it also allowed surgeons to operate with both hands because intermittent manual injection of air was no longer needed for maintenance of pneumoperitoneum.

One of the main areas of uncertainty during this time period was the optimal gas for pneumoperitoneum. The laparoscopic pioneers used room air primarily because it was readily available and cheap. Studies published as recently as 1980 suggested that the creation of pneumoperitoneum with room air was safe and cost-effective.¹³ However, its combustibility, poor solubility in the blood, and concern for venous air embolism have nearly eliminated the use of room air insufflation in today’s operating rooms.¹⁴ Likewise, insufflation with nitrous oxide was popular throughout the 1970s. Yet reports of intra-abdominal explosions have subsequently limited its popularity.¹⁵ Carbon dioxide is currently the most commonly used gas during insufflation. It is odorless, nonflammable, and highly soluble in blood, which reduces the likelihood of air embolisms. Although clinically significant hypercarbia and acidemia can occur, particularly in patients with cardiopulmonary comorbidities, most patients tolerate carbon dioxide pneumoperitoneum without any adverse effects.

To establish standard pressure pneumoperitoneum (typically 12 to 16 mm Hg), the insufflator must first be connected to the carbon dioxide cylinder. Tubing is then used to connect the insufflator to either a Veress needle or a laparoscopic port within the peritoneal cavity. Next, gas flow from the insufflator is initiated. Although the amount of gas needed to create adequate pneumoperitoneum varies according to patient size, abdominal wall compliance, and degree of gas leakage, several liters of carbon dioxide are usually adequate. To maintain pneumoperitoneum throughout a case, substantially more gas is needed. One report estimated that an average laparoscopic colectomy requires approximately 110 to 180 L of carbon dioxide.¹⁶

Most conventional insufflators use an intermittent pressure monitoring system. This allows the insufflator to decrease the gas flow if the intra-abdominal pressure exceeds a preset value. Conversely, it can increase gas flow to account for a

Figure 5 This signal processing unit (camera control unit) can transmit a variety of analog signals (composite or “COMP VIDEO”; Y/C or “S-Video”; “RGB”) and digital signals (“DVI OUT” and “SDI OUT”). Courtesy of KARL STORZ Endoscopy-America, Inc.

loss of gas either externally or through peritoneal absorption. Rather than cycling gas continuously, insufflators alternate between injecting gas every 2 to 3 seconds and monitoring the intra-abdominal pressure. One study that examined different types of low- and high-flow insufflators (9, 10, 16, and 30 L) found that those with high flow rates (e.g., 30 L) compensated for gas leakage better but produced higher intra-abdominal pressure peaks. Flow resistance and the rate of gas leakage, rather than flow capacity, were seen as the critical determinants of intra-abdominal pressure maintenance.¹⁷

The possibility of peritoneal contamination or disease transmission through the flow of intraperitoneal fluid or particulate matter from the patient to the insufflator (and then to the next patient) has been a concern since the early days of laparoscopy. To address this concern, insufflation filters composed of mesh with 0.1- to 0.3-micron pores have been developed. The literature surrounding the effectiveness of these filters is limited. One study published in 1989 reported that rust, dust, and metal filings could be detected on insufflator filters.¹⁸ Another found that the use of a 0.3-micron filter reduced microbial colonization of gas cylinders and insufflators.¹⁹ However, a subsequent examination that used microscopy, mass spectrometry, and bacterial analysis showed no evidence of microbial or particulate matter trapping by the filters.²⁰ To our knowledge, there have been no published reports of disease transmission related to insufflation. However, given the theoretical possibilities of contamination and disease transmission, insufflation filters are commonly used today.

GASLESS LAPAROSCOPY

Despite the near-universal use of insufflators during laparoscopy, a relatively small number of “gasless” laparoscopic cases have been performed since the early 1990s.²¹ Rather than using an insufflator to create pneumoperitoneum, “gasless” laparoscopy involves the use of an abdominal wall retraction system to enhance intra-abdominal visualization. The purported benefits of this technique are the absence of the physiologic risks of pneumoperitoneum, decreased cost, and increased intraoperative flexibility for the surgeon. For example, surgeons can use unlimited suction and can operate with conventional surgical instruments, such as right-angled clamps.²² However, the use of gasless laparoscopy remains uncommon today. This is likely attributable to the favorable safety profile of carbon dioxide pneumoperitoneum and limited visualization if pneumoperitoneum is not established. Additionally, most surgeons are not familiar with the technical aspects of “gasless” laparoscopy, including the retraction setup. There may be a role for gasless laparoscopy in the future, particularly for patients at high cardiopulmonary risk who may have difficulty tolerating carbon dioxide pneumoperitoneum.²¹

Laparoscopic Trocars

There are a wide variety of commercially available laparoscopic trocars, with their own specific characteristics. In general, trocars consist of two different components. The head of the trocar includes a diaphragm to prevent leakage of gas around the inserted instruments and a port for insufflation.

The shaft is the portion that is inserted through the abdominal wall into the abdominal cavity and can vary in both length and diameter to accommodate patients with larger abdominal walls and instruments of various sizes. These components can be purchased either separately or as one unit and can be either disposable or reusable depending on the type of trocar used.

Additionally, all trocars come with an obturator, which inserts through both the head and the shaft to facilitate introduction of the trocar through the abdominal wall. The end of the obturator can be bladed (“cutting trocar”) or nonbladed (“noncutting trocar”). Cutting trocars sharply cut the abdominal wall on entry. They often come with a shield that retracts under force but reengages once that force has dissipated, such as on entry into the abdominal cavity. These trocars tend to create larger defects in the abdominal wall, which can lead to eventual hernia formation. Noncutting trocars also come in a variety of forms, all of which either pass through the abdominal wall bluntly or in a radially expanding fashion and thus leave a smaller fascial defect than cutting trocars of a similar diameter. In one prospective, multicenter, randomized study of noncutting versus cutting trocars in 244 elective laparoscopic procedures, the use of noncutting trocars was associated with significantly lower rates of intraoperative cannula site bleeding and postoperative wound complications. There were no significant differences in operative times or pain scores between the two groups. Although the authors routinely closed 10 mm or greater fascial defects when cutting trocars were used, similarly sized defects in the noncutting group were left open. There were no occurrences of late port-site hernias despite these defects remaining open. Thus, the authors felt that these ports did not require routine closure and likely have a lower rate of port-site hernia formation.²³

Initial trocar placement and establishment of pneumoperitoneum typically occur via either an open technique or a direct puncture of the abdominal cavity. Each technique is associated with its own set of potential complications, and no single technique is absolutely safe. In the open technique, which was first described by Hasson in 1974,²⁴ a small incision is made at the level of the umbilicus and the skin and soft tissue are sharply or bluntly dissected down to the linea alba. The linea alba is then opened sharply, and the peritoneum is opened under direct vision. Once inside the abdominal cavity, stay sutures are placed on the fascia and a blunt-tipped Hasson trocar is inserted into the defect and held in place by the fascial sutures. Pneumoperitoneum is then established through this trocar. Once the procedure is complete, the fascial defect can be closed using the previously placed sutures or with any additional sutures that are necessary to ensure proper closure.

The direct puncture technique employs the use of either a Veress needle to establish pneumoperitoneum or direct trocar placement into the abdominal cavity prior to the establishment of pneumoperitoneum. The Veress needle is a spring-loaded, hollow-bore, self-protecting needle created for accessing the abdominal cavity. When the needle meets resistance, the safety retracts, thus exposing the sharp point of the needle and allowing it to pass through the layers of the abdominal wall. As the needle enters the peritoneum, the resistance is lost and the safety reengages to protect the

intra-abdominal contents. The needle position can then be tested via a saline drop test or connected to the insufflation tubing to assess the opening pressure and initial flow. Once pneumoperitoneum is obtained and additional ports have been placed, the site of Veress entry should always be inspected to ensure that no bowel or vascular injuries have occurred.

Although trocars may be safely inserted into the peritoneal cavity prior to the establishment of pneumoperitoneum, this technique is not employed by many surgeons because of fear of injury to intra-abdominal contents. Within the past decade, several manufacturers have developed “optical trocars.” These optical trocars, which may be bladed or nonbladed, have been designed with a clear tip to allow visualization of the layers of the abdominal wall while the trocar is being inserted. Manufacturers of these trocars contend that this added level of visibility during trocar insertion enhances the safety of trocar insertion. However, randomized data supporting this assertion are currently lacking. As each access technique has its own set of complications, it is helpful for the surgeon to be familiar with a variety of techniques so that he or she may employ the technique most suitable for the specific situation.

Laparoscopic Instruments

In general, laparoscopic instruments are designed such that their end effectors will mimic the instrumentation of open surgery. These end effectors are typically mounted on a 30 cm shaft that measures 5 mm in diameter [see Figure 6]. Some instruments can come on 45 cm shafts designed for use in bariatric surgery, and some are available only in shafts with 10 mm diameters, thus necessitating a larger trocar. Nearly all instruments are designed such that the shaft will rotate through 360° of rotation while keeping the handles stationary. The handles come in a variety of sizes and grip styles and should be trialed to find a set that provides both comfort and proper ergonomics. Additionally, a variety of ratcheting and locking mechanisms are available, and surgeons should find the set that best suits their specific needs.

There are a variety of instruments designed for laparoscopic dissection. The Maryland dissector [see Figure 7] has an end effector that is curved similar to a curved snap and is one of the more popular dissecting instruments. It can be used to dissect ductal and vascular structures but should not be used to grasp delicate tissue as crush injuries may ensue. Additionally, the pointed tips can inadvertently injure intra-abdominal structures, so care must be taken to keep the instrument in view as much as possible. Laparoscopic

Figure 6 A typical laparoscopic instrument. Courtesy of KARL STORZ Endoscopy-America, Inc.

Figure 7 A laparoscopic Maryland dissector. Courtesy of KARL STORZ Endoscopy-America, Inc.

right-angled dissectors are also available for dissection of vascular and ductal structures. Blunt graspers come in a wide variety of shapes and sizes. Some, such as the laparoscopic Babcock grasper [see Figure 8], are designed to be atraumatic and are used for the manipulation of most intra-abdominal structures. Others are more traumatic, such as the laparoscopic Allis grasper, but allow for a stronger purchase on tougher or thicker tissue, such as the gallbladder. Laparoscopic biopsy forceps, needle drivers, scissors, staplers, clip applicators, probes, sponges, and retractors are also all commercially available in a wide variety of forms. It is worthwhile to become familiar with several different instruments as instrumentation will likely vary between institutions.

Laparoscopic Energy Sources

The energy sources used to obtain hemostasis in laparoscopic surgery are similar to those employed in open surgery. Monopolar, bipolar, and ultrasonic energy sources all come in forms suitable for use in laparoscopic cases. Bipolar and ultrasonic energy sources have significantly decreased operative times for more complex laparoscopic cases as larger vessels can now be controlled with these instruments rather than with staplers, Endo-Loops (Ethicon Endosurgery, Cincinnati, OH), or laparoscopic suturing. Although the physics principles that govern these energy sources are the same in open and laparoscopic surgery, there are several aspects of laparoscopic surgery that have unique implications and merit further discussion.

When using monopolar electrocautery, an alternating current of 50,000 Hz is created in a generator and is passed onto an active electrode, through the patient, and eventually back to the generator via a return electrode. Significant heat will be generated in the tissue adjacent to the active electrode. Thus, the active electrode should have a very small surface area (such as a hook or the tip of a Maryland dissector) to allow the electricity to be focused on a small area. Conversely, the return electrode, which is the grounding pad normally placed on the patient's lower extremity, should have a large

Figure 8 A laparoscopic Babcock grasper. Courtesy of KARL STORZ Endoscopy-America, Inc.

surface area so that minimal heat is generated at the site and no inadvertent thermal injuries occur.

In open surgery, it is standard practice to grasp a bleeding vessel with a pair of forceps and then touch the forceps with the tip of the electrocautery to obtain hemostasis. This phenomenon of electrical transference from the active electrode to another conducting instrument is referred to as direct coupling. In laparoscopic surgery, direct coupling can occur purposefully but can also occur inadvertently when an instrument is placed in close proximity to another instrument that is electrically active. The current may transfer to the nonactive instrument or any other metal substance, including the laparoscope itself. These instruments may then discharge their electrical current to surrounding structures, resulting in accidental thermal injuries. Thus, whenever monopolar electrocautery is being employed, it is important to ensure that there is a safe distance between the active instrument and all other metallic objects. Additionally, if there are disruptions in the insulation of the active instrument, electricity may be discharged to surrounding structures through these cracks, again leading to inadvertent thermal injury. The Insulscan (Medline Industries, Mundelein, IL) is a device designed to look for insulation disruptions in laparoscopic instruments. Although it does add time to the setup of the case as instruments must be passed through the unit individually, it may aid in preventing thermal injuries, which could require significantly more time to repair laparoscopically.

In addition to direct coupling, capacitive coupling can occur in laparoscopic cases where metal trocars are being used. Capacitive coupling occurs when two conductors are separated by a nonconductor. If the active electrode of a laparoscopic instrument is inserted through a metal trocar, the insulation surrounding the instrument acts as a nonconductor and can function as a capacitor. The capacitor generates an electrostatic field between the active electrode and the metal trocar. As electricity passes through the active electrode, the electrostatic field can transfer energy to the metal trocar, which will then discharge the energy in the form of heat, leading to burns of the skin and abdominal wall. The use of nonconductive plastic trocars will avoid this phenomenon.

Two bipolar energy sources are now commercially available for laparoscopic use. These devices, the LigaSure (ValleyLab, Boulder, CO) and the EnSeal (Ethicon Endosurgery), both pass low-voltage, high-frequency current between two active electrodes at the tips of the instruments. According to the manufacturers, the tissue between these two electrodes is effectively coagulated and sealed for vessels as large as 7 mm in diameter. Both instruments include a blade to divide the tissue once it has been coagulated. The instruments themselves generate very little heat, so there is minimal lateral spread of thermal injury.

Ultrasonic shears use mechanical energy rather than electrical current to seal vessels and divide tissue. The most commonly used device is the Harmonic Ace (Ethicon Endosurgery), which requires a generator that produces an electrical signal, which in turn is converted into a mechanical vibration at a frequency of 55,500 Hz. This mechanical vibration is amplified as it travels down the shaft of the instrument and into the active blade of the device, which generates heat to coagulate vessels and divides tissue without requiring a

separate knife for cutting. The active blade of the instrument will remain hot for some time after use, and direct contact with surrounding tissues should be avoided.

Diamantis and colleagues compared the various sources of energy by using monopolar electrocautery, bipolar electrocautery, the LigaSure, and the UltraCision (Ethicon Endosurgery, ultrasonic shears) to ligate the short gastric vessels in rabbits.²⁵ They found that monopolar and bipolar electrocautery frequently failed to achieve adequate hemostasis and resulted in significant thermal spread, leading to perforation of the adjacent gastric wall. The LigaSure and UltraCision devices successfully coagulated 100% of the vessels for which they were used. Both modalities had minimal side thermal injury, but the LigaSure had slightly less histologic evidence of inflammation and thermal injury than the UltraCision on postoperative days 7 and 14. These two modalities were clearly safer and more effective than either monopolar or bipolar electrocautery.²⁵

Troubleshooting Laparoscopic Equipment

Although few studies have measured the frequency, etiology, cost, or clinical impact of laparoscopic equipment misuse and malfunction, equipment problems during laparoscopic surgery are quite common. One study that used video recording during 30 laparoscopic cholecystectomies found that 90% of cases were affected by a problem with the basic technical equipment.²⁶ Fifty-five percent of these incidents were the result of equipment malfunction related to an equipment defect, improper device setting, or faulty connection. Another study that examined 62 laparoscopic cases concluded that at least one equipment failure occurred in 42% of cases.²⁷ Human error contributed to nearly half of these failures.

Given the multitude of potential sources for equipment failure, a systematic approach to equipment troubleshooting is key. In this section, we discuss some of the most common equipment problems that the surgeon may experience in the operating room and offer a methodical approach to address these issues [see Table 1].

IMAGES ON THE VIDEO MONITOR ARE TOO DARK

The light source, light cable, laparoscope, camera, and video monitor must all function optimally to provide video images with adequate lighting. If the lighting is poor, several steps can be taken to address the issue. Blood will absorb a significant portion of the light, making the overall image appear darker; thus, blood should be cleared from the field if possible. Next, connections between each of the components should be checked to ensure that each component is properly attached to the system. In the aforementioned observational study of laparoscopic cholecystectomies, “faulty” equipment connections were present in nearly one third of cases.²⁶ If the connections are intact, the current settings for both the video monitor and the light source should be checked. If the settings on the video monitor have been altered (e.g., brightness), they should be adjusted back to the default settings. The light intensity from the light source can also be increased. While making this adjustment, the surgeon should note the number of hours that the current light bulb has been in use. Many light sources display this number on the front of the machine. If the number of hours exceeds the accepted life

Table 1 Laparoscopic Equipment Troubleshooting

Main Problem	Equipment Issue	Relevant Equipment	Troubleshooting Maneuver
Images on the video monitor are too dark	A connection between two pieces of equipment is faulty	Light source, light cable, laparoscope, camera, video monitor	Confirm that each piece of equipment is properly connected to the system
	Improper setting (e.g., brightness, gain)	Video monitor, camera, light source	Adjust back to default settings
	Poor light intensity from the light source	Light source	Ensure that bulb is within accepted life span; increase intensity of light source or replace bulb
	Light intensity from the source is adequate, but light from the laparoscope tip is poor	Light cable, laparoscope	If there are numerous breaks in the fiberoptic bundles of the light cable, replace the cable; if not or if the fiberoptic bundles cannot be inspected, replace either the cable or the scope and assess for improvement in light intensity
Images on the video monitor are foggy or blurry	Laparoscope is not focused	Laparoscope, camera	Focus the laparoscope
	Condensation is present on the tip of the laparoscope	Gas warming/humidifying devices, laparoscope, warming devices, antifogging solutions	Use of any of these warming or antifogging techniques is reasonable (although data are lacking)
	Liquid or particulate matter is present on the tip of the laparoscope	Laparoscope	Wipe the tip of the laparoscope off (ideally using gauze rather than the viscera)
	Smoke is obscuring the surgical field	—	Open one of the ports to let smoke escape
	Condensation has accumulated within the laparoscope or coupler	Laparoscope, coupler	Detach laparoscope from camera (and coupler if possible) and wipe lens; if condensation is within the scope lens system, the scope should be replaced
Images on the video monitor are abnormally colored	Improper setting (e.g., color, brightness)	Video monitor	Adjust back to default settings
	White balancing has not been performed correctly	Laparoscope, camera, camera control unit	White balance the laparoscope
	Video monitor has become magnetized	Video monitor	“Degauss” the video monitor (applies to cathode ray tube systems only)
There is no image on the video monitor	Connection between two pieces of equipment is faulty, or a piece of equipment is not turned on	Light source, light cable, laparoscope, camera, video monitor	Confirm that each piece of equipment is properly connected to the system and is turned on
	Analog or digital cables are not correctly plugged in	Video signal processor, analog or digital cable, video monitor	Ensure that the cables are plugged into the appropriate “out” connector of the signal processing unit and the “in” connector of the video monitor
	Light bulb has burned out	Light source/bulb	Replace the light bulb
Abdominal insufflation is inadequate	No gas in the cylinder	Gas cylinder	Replace the cylinder
	Cylinder valve is closed	Gas cylinder	Open the cylinder valve
	Veress needle or trocar is not within the peritoneal cavity	Veress needle or trocar	Place Veress needle or trocar into the peritoneal cavity
	Something is compressing the insufflation tubing	Insufflation tubing	Remove source of external compression
	Stopcock on the trocar is set to block airflow	Trocar	Adjust stopcock so that gas flow may proceed
	Flow rate or maximum insufflation pressure settings are incorrect	Insufflator	Adjust flow rate or maximum insufflation pressure appropriately
	Incompatibility between insufflator and filter	Insufflator, filter	Ensure that the filter is compatible with insufflator (relevant for high-flow insufflators)
	There is an air leak somewhere in the system	Trocars	Ensure that gaps between trocars and fascia are minimized; close valves on ports so that intraperitoneal gas does not escape
	Inadequate abdominal wall relaxation	None	Additional sedation or paralytic

span for that bulb, the bulb should be replaced. Room light sources should also be dimmed if their brightness is impairing the quality of the video monitor images.

If troubleshooting maneuvers targeted toward the connections, settings, and light source do not resolve the issue, the light cord and laparoscope should be evaluated. Breaks in the fiberoptic bundles can cause degradation in the quality of the images. Some lighting cables have a transparent covering that allows these breakages to be seen. These will appear as points of light along the length of the cable. If there are numerous breaks in the bundles, the cable should be replaced. If there are no visible breakages, the laparoscope should be replaced and the effect on the video image should be noted. Some surgeons also recommend setting the light source and camera shutters to “manual” in poor lighting scenarios.¹⁰ An improvement in the image quality following either of these maneuvers reflects a problem with the shutter in either the light source or the camera, respectively.

The brightness of the light that is emitted from the laparoscope tip can be deceiving. The light may appear to be bright enough when simply looking at the tip, but this does not ensure that the intensity is adequate. Additionally, although the surgeon may be tempted to increase either the gain on the camera control unit or the brightness on the monitor, these maneuvers should be performed with caution. They may increase the image brightness on the monitor, but the need to perform these steps suggests that there is a defect somewhere in the system. Increasing either the gain or brightness can also reduce the image quality.

IMAGES ON THE VIDEO MONITOR ARE FOGGY OR BLURRY

Foggy or blurry images on the video monitor are a common cause of impaired visualization during laparoscopic surgery. One reason for a blurry image is that the laparoscope simply is not focused. To prevent this problem, surgeons can focus the laparoscope before it is inserted by pointing the laparoscope at an object on the surgical field, such as a piece of gauze or a suture packet. Alternatively, the scope can be focused after insertion into the abdomen (e.g., using the liver as a focal point).

Perhaps the most common cause of blurry imaging is the presence of liquid, particulate material (e.g., adipose tissue), or smoke on either the laparoscope lens or in the surgical field. Liquids such as irrigation fluid, ascites, and blood can all obscure the surgical field. Condensation on the laparoscope lens is probably the most common cause of lens fogging because of liquids. This condensation forms on the lens because the temperature of the lens (i.e., the laparoscope) is usually lower than body temperature during the establishment and maintenance of pneumoperitoneum. Given that the intra-abdominal humidity typically ranges from 85 to 95% during laparoscopy, the presence of lower temperatures near the front lens causes the dew point to be reached, which results in the production of condensation on the lens.²⁸ At an intra-abdominal humidity of 85%, the scope temperature must exceed 93°F to prevent lens condensation. Some recommend maintaining a scope temperature of at least 98.6°F.²⁹

Given these observations and recommendations, there has been a substantial amount of interest in the use of warmed (typically 98.6 to 113°F) and humidified (50 to 95%) gas. If

gas flows directly from the insufflator to the patient (without warming or humidification), it will enter the peritoneal cavity at approximately 70°F and 0% humidity. On the other hand, if warmed, humidified gas is sent from the insufflator (or gas is sent from the insufflator through a warming, humidification system and then to the patient), it can enter the peritoneal cavity at body temperature.¹⁶ In addition to the potential benefit of improved visualization attributable to condensation prevention, there is some evidence that warm, humidified gas can also reduce hypothermia and pain.^{30,31} However, several randomized controlled trials have failed to show either a clinical benefit or a decrease in lens fogging with the use of warmed, humidified air.^{16,32–34} Although the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) has not issued formal recommendations regarding this issue, the European Association for Endoscopic Surgery guidelines for pneumoperitoneum state that the clinical effects of warmed, humidified gas are “minor” and the data regarding its influence on pain are “contradictory.”³⁵

Additional maneuvers to reduce laparoscopic lens fogging include laparoscope warming and the use of antifogging solutions. Numerous warming techniques have been described, including placing the scope into a container of warm liquid, using warm sterile towels, or even modifying the scope to include a built-in warming mechanism. Antifogging solutions, such as the Fog Reduction and Elimination Device (FRED; Covidien Autosuture, Mansfield, MA) and Reso-clear (Resorba Wundversorgung; Nuremberg, Germany), have also been developed and used extensively. Although these maneuvers are anecdotally effective and have strong face validity, definitive data regarding these laparoscopic warming techniques and antifogging solutions are lacking.³⁶

Wiping the laparoscope tip on the viscera—often the liver or small bowel—is another maneuver that is commonly used and is often effective. However, this should be performed cautiously as laparoscope tip temperatures can exceed 200°F. One study found microscopic evidence of thermal injury to the bowel after only 5 seconds of direct contact between the laparoscope and viscera.⁷

Moisture can also accumulate at various points within the system, including between the laparoscope lenses, on the eyepiece of the laparoscope, and on the coupler. Condensation on the eyepiece and coupler can be addressed by detaching the camera (and coupler if possible) and wiping the lenses. Condensation between the laparoscope lenses suggests a malfunction in the seal and will most likely require laparoscope replacement and repair.

IMAGES ON THE VIDEO MONITOR ARE ABNORMALLY COLORED

When presented with this scenario, the surgeon should first ensure that the monitor settings are correct. The previous surgical team may have intentionally changed the monitor settings during a previous case, or maintenance staff could have inadvertently changed the settings between cases. The surgeon should also ensure that the camera has been “white balanced” appropriately. White balancing is typically performed by placing a white object, such as gauze, in front of the laparoscope-camera unit. After focusing on this white object, a white balance button can be pushed on either the camera head or the camera control unit. This maneuver

allows the camera to set the video output voltage levels so that a white image is created when the scope is targeted on a white object.³⁷ If white balancing is omitted or performed incorrectly, the images on the video monitor may appear abnormally colored.

Traditional video monitors that use a cathode ray tube can also become magnetized over time, creating distorted colors and images. This often appears as a purplish discoloration around the image.¹⁰ Although most monitors will automatically remove the magnetic forces when turned on (referred to as “degaussing”), manual degaussing may need to be performed as well. Many video monitors have manual degauss buttons for this reason.

THERE IS NO IMAGE ON THE VIDEO MONITOR

This scenario usually occurs when a component in the system is improperly connected or not powered on. The surgeon should first ensure that the light source, signal processing unit (camera control unit), and video monitor are all turned on and properly connected to each other. The bulb in the light source should also be checked to ensure functionality. Next, the connections between the signal processing unit and the video monitor should be inspected to ensure that the analog or digital cables are connected to the appropriate “out” or “in” connectors. These cables are typically plugged into the “out” connector of the signal processing unit and the “in” connector of the video monitor. Similarly, if a second video monitor is used, the monitor-to-monitor cable should be plugged into the “out” connector of the first monitor and the “in” connector of the second monitor. Finally, the analog or digital signal connector that the video cable is plugged into should match the type of video signal that is selected on the monitor interface. These recommendations are summarized succinctly in the *SAGES Laparoscopy Troubleshooting Guide*.³⁸

ABDOMINAL INSUFFLATION IS INADEQUATE

Before insufflation is initiated, the surgical team should ensure that the amount of gas in the cylinder is adequate and the cylinder valve is open. The surgeon should verify that the Veress needle or the laparoscopic trocar is within the peritoneal cavity rather than the preperitoneal space, retroperitoneum, omentum, or another intra-abdominal structure. Insufflation into a location other than the peritoneal cavity usually results in low or absent flows and high pressures. Once intraperitoneal placement of the access device has been achieved, insufflation can proceed at a flow rate selected by the surgeon. If the gas flow remains poor, the team should ensure that the insufflator, the insufflation tubing, and the Veress needle or trocar are connected appropriately. Sources of external compression on the tubing should be addressed, and if the tubing is connected to a trocar, the stopcock on the

trocar should be adjusted to allow for insufflation. The minimal flow rate and maximal intra-abdominal pressure should also be checked.

Incompatibility between the insufflator and the filter or blockage of the filter can also cause a disruption in gas flow. In this scenario, the insufflator senses a high intra-abdominal pressure and consequently reduces flow, which leads to inadequate pneumoperitoneum. This is mainly an issue for high-flow insufflators (30 to 40 L per minute) because specialized filters may be needed to accommodate the high flow rates. Although many companies have addressed this issue by manufacturing compatible tubing and filters, the surgical team must be mindful of this problem, particularly in settings where products from multiple manufacturers are used.

Once the desired intra-abdominal pressure has been reached, the surgeon may have difficulty maintaining an adequate pneumoperitoneum. In addition to performing each of the steps outlined above (i.e., checking the gas cylinder, sources of tubing compression, ensuring that stopcocks on additional trocars are closed), the surgeon should ensure that there are no leaks around the trocar sites or through the trocars themselves. If leaks are detected around the trocar sites, gaps between the trocars and the surrounding fascia and abdominal wall tissue should be minimized or occluded. Additional fascial sutures may be needed. If air is leaking through a trocar, the trocar cap should be checked to ensure that it is properly secured to the shaft. If leakage persists, an instrument should be inserted and removed to realign the diaphragm with the trocar. If these measures fail to resolve the problem, the trocar may need to be replaced. Adequate abdominal muscle relaxation should also be confirmed. If the surgeon suspects inadequate relaxation (the patient is moving or the abdominal wall appears to be “tight”), a discussion with the anesthesia team regarding additional sedation or paralysis is appropriate.

Conclusion

As laparoscopic procedures continue to increase in frequency and complexity, it will become progressively more important to be mindful of these simple troubleshooting maneuvers to keep these procedures flowing smoothly and safely. Although surgeons must have intricate knowledge of their laparoscopic instrumentation, it is equally important for the other members of the surgical team to be familiar with both the equipment and the myriad of potential problems that can arise during these procedures. When all members of the surgical team can work together to quickly overcome any equipment issues during laparoscopic cases, operating room efficiency will improve and better outcomes can be anticipated.

22 PRINCIPLES AND TECHNIQUES OF ABDOMINAL ACCESS AND PHYSIOLOGY OF PNEUMOPERITONEUM

Jon C. Gould, MD, FACS, and Ancil Philip, MD

Abdominal Access in Laparoscopic Surgery

When compared with the open approach to many abdominal operations, the laparoscopic technique is often associated with decreased morbidity and a quicker recovery. Unfortunately, there are also specific complications related to the laparoscopic approach that would not necessarily be seen with a laparotomy. Many of the most significant complications occur very early in the operation during the act of attaining abdominal access.

There are three general types of laparoscopic access, with many variations and modifications. The Veress needle technique is the oldest and most traditional method of laparoscopic entry. The direct trocar insertion technique involves direct penetration of the fascia and peritoneum by the trocar. Finally, in the open or Hasson technique, a minilaparotomy is performed so that the initial trocar can be placed under direct visualization.

VERESS NEEDLE ACCESS

Molloy and colleagues assessed 155,987 gynecologic procedures and reported that the Veress needle was used in 81% of them.¹ In addition, of the 17,216 general surgery procedures assessed, the Veress needle was used in 48%, whereas in the remaining 52%, other methods were used. Kelling first described preliminary insufflation of the peritoneal cavity prior to trocar placement in 1901.² The Veress technique remains popular today. In the Veress technique, gas is insufflated until an adequate volume has been added to create space in the peritoneal cavity between the abdominal wall and the intra-abdominal as well as the retroperitoneal organs. Once insufflation is complete, a sharp trocar is placed into the peritoneal cavity. In the blind technique, a bladed trocar is inserted into the insufflated peritoneal cavity without direct visualization. A modification of this technique involves the use of a trocar into which a laparoscope can be inserted. Visualization of the abdominal wall layers and the insufflated peritoneal cavity is possible because of the clear tip of these optical-viewing trocars.

Janos Veress first introduced the spring-loaded needle currently used to introduce pneumoperitoneum, originally to induce pneumothorax.³ Modern needles are 12 to 15 cm long, with an external diameter of 2 mm. The outer cannula of a Veress needle consists of a beveled needle point for cutting through tissues. A spring-loaded inner stylet is located

within the outer cannula [see Figure 1]. The tip of the inner stylet is dull, protecting the viscera from injury by the sharp outer cannula. Direct pressure on the tip of the Veress needle pushes the dull stylet into the shaft of the outer cannula. When the tip of the needle enters a space such as the peritoneal cavity, the dull inner stylet springs forward.

Technique

The location on the abdominal wall selected for initial Veress placement depends on a variety of factors. The type of procedure, location of previous incisions, and patient's body habitus may all have an influence. The initial trocar does not always need to be placed through the same incision as the Veress needle, although this is the most common practice. The advantage to using the same site includes the fact that easy Veress placement and insufflation in a particular location provides some level of reassurance that this is a safe site. Prior to insertion of the Veress needle, it is a good practice to ensure that the stomach is decompressed with a gastric tube as gas is often insufflated into the stomach during induction of anesthesia. A large, gas-filled stomach can be injured by the Veress needle or primary trocar. The distended stomach may also displace other intra-abdominal organs, putting these at increased risk for injury.

The abdominal wall is relatively thin in the periumbilical location, and the umbilicus is tethered to the fascia, making this an ideal location for initial Veress access. An alternative location (e.g., subcostal) or a different technique (open Hassan) may be best in patients with a prior midline incision near the umbilicus. Insertion of the Veress needle and primary trocar through a site in the left upper quadrant is recommended by some surgeons to decrease the risk of complications related to intra-abdominal adhesions.^{4,5} The

Figure 1 Veress needle.

left upper quadrant insertion site (Palmer point) is located 3 cm below the middle of the left costal margin.⁶ Anatomic studies indicate that the abdominal wall is uniformly thin in this location and the distance from the skin to the retroperitoneal structures is greater than 11 cm in most patients.⁷ For the periumbilical Veress needle insertion, a skin incision is made, typically of sufficient size to easily accommodate the intended trocar to be placed at this site. Penetrating towel clips can be placed in the skin near the incision and used to elevate the abdominal wall. This maneuver helps create some space between the anterior aspect of the peritoneal cavity and the intra-abdominal contents as well as the retroperitoneal major vascular structures. It also minimizes the chance for downward pressure with the Veress needle to push the fascia closer to these vital structures. In obese patients, there is a tendency for the skin and subcutaneous fat to be lifted instead of the fascia with this towel clip maneuver. Because of this, a slightly larger incision is sometimes necessary. The base of the umbilicus or the fascia itself should be grasped. Now that the fascia is elevated, the surgeon takes the Veress needle and advances it at a right angle to the fascia. The needle is advanced until there is a perceptible change in force as the needle penetrates the fascia and enters the peritoneal cavity. An audible click is usually heard or felt as the spring-loaded tip advances into the peritoneal cavity. A surgeon should feel or hear two clicks as a Veress needle is placed through the abdominal wall. The retracted blunt needle tip will suddenly extend after it passes through the anterior rectus abdominus fascia and again when it enters the peritoneal cavity.⁸ In the waggle test, the hub of the Veress needle should move freely about a fulcrum point located within the anterior abdominal wall. Lack of free movement suggests that the needle tip has entered an intraperitoneal or retroperitoneal structure and the needle should be partially withdrawn. Opponents of this maneuver point out that, if done forcefully, it is likely to enlarge an injury to a fixed vessel or viscus.⁹ It is also likely, however, to alert surgeons to the possibility of retroperitoneal placement before insufflation.

Drop test A syringe partially filled with saline is attached to the Veress needle. The first maneuver is to aspirate the syringe. The appearance of blood indicates that a blood vessel was entered. The needle can be removed and reinserted, with the procedure continuing in the absence of hemodynamic instability.¹⁰ The aspiration of enteric fluid indicates that the needle has been placed into bowel. It is best to leave this needle in place to identify the specific segment of bowel that has been injured. Options at this point include converting to an open procedure or inserting a second Veress needle in a different location and establishing access in this alternate location. The location of the Veress needle should be ascertained and any bowel injury immediately repaired. In the event that no obvious perforation is found, several options exist. The procedure could be aborted at this point followed by close clinical observation (may be considered in laparoscopic incisional hernia procedures where a permanent prosthetic will be placed into the peritoneal cavity). A laparotomy could be made to continue the search for the possible bowel injury. The final option is to continue with the procedure laparoscopically as planned. The risk with the latter approach is of delayed peritonitis from an unrecognized bowel injury,

and caution should be employed if this option is selected. Any signs of postoperative peritonitis or early sepsis should be taken seriously and investigated thoroughly in these cases.

In the absence of blood or enteric fluid, saline is then injected. The inability to inject saline suggests that the tip of the needle may be in a tissue plane. Next, the saline drop test is performed to further assess the location of the tip of the needle [see Figure 2]. A drop of saline is placed in the hub of the needle while maintaining abdominal wall elevation. The passage of saline through the needle is consistent with the tip of the needle being located in the peritoneal cavity. It is important to realize that a successful drop test does not rule out the possibility that the tip of the needle is in bowel.¹¹

Insufflation Once these placement tests are completed to the satisfaction of the surgeon, the gas tubing is connected to the Veress needle, and insufflation is commenced at a low rate of flow (5 mm Hg) while continuing to elevate the abdominal wall. Once insufflation is initiated, it is important to note both the flow rates and the intra-abdominal pressure. The measured pressure will vary according to the length and size of the needle, depth of anesthesia, patient's body habitus, and location of the tip of the needle. A flow rate of zero and a pressure of 20 mm Hg or more indicate that the tip of the needle is not situated freely within the peritoneal cavity. The most likely locations include the abdominal wall or an intra-abdominal organ such as the omentum. In the latter case, lifting the abdominal wall further and slightly angulating the needle may free the tip to allow insufflation to proceed. The needle should not be advanced further without withdrawing it completely and beginning the entire sequence described above from the beginning because of the risk of penetrating the retroperitoneum.

Once insufflation is begun, the strongest predictor of intra-peritoneal placement seems to be an initial filling pressure of less than 10 mm Hg.¹² If the initial intra-abdominal pressure is low and flow seems to be occurring through the needle, the flow rate on the insufflator can be set to a higher rate. Many high-flow insufflators can accommodate flow rates up to 40 L/min, but flow rates in excess of 1 to 2 L/min are rarely

Figure 2 Saline drop test.

exceeded through the long, narrow Veress needle. During insufflation, it is important to continue to observe the abdominal wall morphology, flow rates, volume insufflated, intra-abdominal pressure, and patient's vital signs. Eccentric elevation of the abdominal wall may suggest extraperitoneal insufflation or insufflation into a visceral structure such as the stomach or another piece of small or large bowel. Percussion for tympany is a useful maneuver for ensuring uniform insufflation of the abdominal cavity.

Trocar insertion After an adequate volume of gas has been insufflated, the Veress needle is removed. In the blind technique for initial trocar insertion, a bladed trocar is inserted through an adequately sized incision. The operating table should be set to a height that allows the surgeon to adequately control the force and vector of initial trocar placement. When the table is placed too high, the surgeon must elevate his or her arm, resulting in reduced control and perhaps a greater risk of injury. Countertraction on the abdominal wall should be maintained to minimize the chance of intra-abdominal injury from the trocar blade. Bladed trocars are equipped with a spring-loaded safety shield that retracts when passed through the abdominal wall. Bladed configurations vary by manufacturer, and the recommended technique for trocar insertion differs as well. Trocars with a three- or four-sided blade shaped like a pyramid are placed by steadily rotating the trocar back and forth as the blade is advanced. Disadvantages to these trocars include the large size of the fascia defect created. Incisional trocar-site hernias may be more common with pyramidal than with conical or flat trocar blades. In one comparative study, the risk of incisional hernia was more than 10 times greater when a disposable pyramidal device was used than when access was gained with a reusable conical trocar cannula system (1.83 versus 0.17%).¹³ Potential advantages to the pyramidal-bladed trocars may include the possibility that less force is required to access the abdominal cavity than other blade configurations.¹⁴ Conical flat-bladed trocars [see Figure 3] are placed with direct axial pressure and little rotation. The advantage to bladed trocars with this configuration is that for smaller trocars, the fascia defect is so small that it does not need to be closed at the end of the case. During bladed trocar insertion, a perceptible change in the insertion force signals entry into the peritoneal cavity. This is often accompanied by an audible click as the blade retracts. Advancement of the trocar is halted at this

point. The bladed trocar is removed from its outer cannula. If the insufflation port on the cannula is opened, an audible hiss of escaping gas indicates that the tip of the cannula is located in the insufflated peritoneal cavity. The laparoscope is then inserted through this port, both to confirm the successful placement of the cannula in the peritoneal cavity and to rule out intra-abdominal injury from either Veress needle or trocar insertion. If the cannula is located in the peritoneal cavity, the gas tubing is connected to the gas port of the cannula, and insufflation commences through this port to the set pressure (typically 15 mm Hg). The remaining cannulas are then placed under direct visualization from within the peritoneal cavity.

The Veress technique can also be used to place a primary optical-viewing trocar. Optical trocars can be bladed or bladeless [see Figure 4]. As is the case for the bladed trocars, insertion techniques vary according to trocar tip configuration.¹⁵

DIRECT TROCAR INSERTION

In the direct insertion technique, the primary trocar is placed without preinsufflation. This can be performed with either a bladed trocar and a blind technique or an optical trocar under some measure of direct visualization. Theoretical advantages include decreased time to establish abdominal laparoscopic access.¹⁶ Potential disadvantages may include a higher rate of trocar-related intra-abdominal injuries. Several published series evaluating the direct trocar placement technique have demonstrated that very low rates of injury are possible.¹⁷ This technique is safe in the hands of experienced laparoscopists—those most likely to publish their results. For inexperienced surgeons, the direct access technique is likely associated with unnecessary increased risk when compared with alternative techniques.^{1,18,19}

Technique

If a bladed trocar is selected, it is important to ensure that the patient is completely relaxed, that the skin incision is sufficiently large, and that adequate countertraction on the fascia is maintained during placement. When a bladed trocar with a safety shield is used as described above, a change in resistance signifies that the tip of the trocar may be in the peritoneal cavity. Prior to the initiation of insufflation, the laparoscope should be inserted into the cannula. If the

Figure 3 Conical flat-bladed trocar.

Figure 4 Nonbladed optical trocar.

peritoneal cavity has been safely entered, insufflation can commence at a high rate of flow. If the cannula has not entered the peritoneal cavity, it should be removed and the sequence above reinitiated from the beginning or an alternate technique such as a Veress or open access technique selected.

Optical trocars can also be placed with a direct technique. Once again, the patient needs to be completely relaxed, an adequate skin incision should be made, and adequate countertraction should be applied. A gradual twisting motion is employed, and distinct layers of the abdominal wall can be seen during entry.²⁰

OPEN (HASSON) ACCESS

In an effort to decrease the incidence of injuries associated with the blind penetration of the abdominal cavity during laparoscopy, Hasson proposed a blind minilaparotomy technique.²¹ He developed a reusable device similar to a standard laparoscopic port with a cork-shaped sleeve on the outside. The sleeve could be slid up or down on the cannula shaft depending on the thickness of the patient's abdominal wall. Sutures in the fascia were used to anchor the outer sleeve and to create an airtight seal. Disposable Hasson cannulas are currently available. Hasson-type cannulas that are fixed to the abdominal wall between a balloon and a dense foam cuff are also commercially available [see Figure 5]. Regardless of the configuration of the cannula, the basic method for peritoneal access in the open technique remains the same.

In the open technique, the peritoneal cavity is entered under direct visualization. Theoretical advantages to the open technique may include a decreased likelihood of injury to adherent bowel,^{5,22} although this has been a matter of debate. Major vascular injuries during initial trocar insertion are likely minimized with the open technique, although they can still occur. Potential disadvantages may include increased operative time (especially in obese patients) and an increased risk of late port-related complications such as hematoma, wound infection, or hernia.⁷ Leakage of gas around the cannula is occasionally a problem, but balloon-tipped cannulas and high-flow insufflators prevent these issues from being clinically significant.

Technique

The periumbilical location is most often chosen for initial Hasson cannula placement. An adequately sized incision is made, and the abdominal wall fascia is identified. Two Kocher clamps are secured to the fascia on either side of the midline linea alba. The Kocher clamps are elevated, and the abdominal fascia is incised vertically in the midline. An

Figure 5 Hasson cannula.

approximately 1.5 to 2.0 cm defect is created in the fascia. If the defect is too large, air leakage may be a problem. Depending on the patient's body habitus, it may be easy to become lost in the preperitoneal space. Entry into the peritoneal cavity should be confirmed visually. Two heavy sutures should be placed in either side of the fascial defect prior to releasing the fascia from the Kocher clamps. The Hasson cannula with its blunt obturator is advanced into the peritoneal cavity, and the sutures are firmly attached to the fixation obturator. Gas is insufflated through the cannula at a high rate of flow, and the laparoscope is inserted.

If gas leaks excessively around the cannula, there are several techniques for addressing this. The first option is to remove the stay sutures and secure these to the cannula more firmly. A penetrating towel clip can be used to seal the skin around the cannula. The cannula can be removed, and another fascial suture can be placed and tied to decrease the size of the fascial opening. Finally, a balloon-tipped fixation trocar can be placed to seal the leak.

COMPLICATIONS

Insertion of the Veress needle and primary trocar for initial entry remains the most hazardous part of laparoscopy, accounting for 40% of all laparoscopic complications and the majority of the fatalities.²³ Despite decades of research and development to find safer methods for initial laparoscopic entry, major vessel injuries have been reported using virtually all types of trocar insertion methods. The overall morbidity and mortality rates related to laparoscopic access are low. The life-threatening complications include injury to the bowel, bladder, major abdominal vessels, and anterior abdominal wall vessel. Injuries to the bowel (1.8 per 1,000 cases) are most common, followed by injuries to the abdominal vessels (0.9 per 1,000 cases).²⁴ A recent Cochrane review included 17 randomized, controlled trials concerning 3,040 individuals undergoing laparoscopy. Overall, there was no evidence of advantage using any single abdominal access technique in terms of preventing major complications. However, there were two advantages with direct trocar entry when compared with Veress needle entry in terms of avoiding extraperitoneal insufflation (odds ratio [OR] 0.06, 95% confidence interval [CI] 0.02 to 0.23) and failed entry (OR 0.22, 95% CI 0.08 to 0.56). There was also an advantage with radially expanding access system (Step bladeless trocars, Covidien, Norwalk, CT) trocar entry when compared with standard trocar entry in terms of trocar site bleeding (OR 0.06, 95% CI 0.01 to 0.46). Finally, there was an advantage of not lifting the abdominal wall before Veress needle insertion when compared with lifting in terms of failed entry without an increase in the complication rate (OR 5.17, 95% CI 2.24 to 11.90). However, studies were limited to small numbers, excluding many patients with previous abdominal surgery and women with a raised body mass index, who often had unusually high complication rates. The authors concluded that there appears to be no evidence of benefit in terms of the safety of one technique over another. However, the included studies were small and cannot be used to confirm the safety of any particular technique.²⁵

Vascular Injury

Vascular injury can occur regardless of the method of access, largely because of the relatively close proximity of the

abdominal wall to the great vessels that are located retroperitoneally, which, in thin individuals, can be as little as 2 cm.²⁶ Most vascular injuries (up to 80%) occur at the initial access.⁵ Recent studies have suggested that the incidence of major vascular injury is slightly higher with the closed technique (Veress and direct trocar insertion) as opposed to the open (Hasson) technique. Molloy and colleagues' study suggests that the open technique decreased the rate of vascular injury to 0.01% compared with a rate of 0.04% associated with closed techniques using a Veress needle.¹ A recent systematic review specifically evaluating injuries related to Veress needle insertion included 38 selected articles, 696,502 laparoscopies, and 1,575 injuries (0.23%). Of these injuries, 98 (6.2%) involved blood vessels, 8 (8.1%) of which were injuries to major retroperitoneal vessels.²⁷ Although the incidence of major vascular injuries is low, the mortality rate arising from these lesions reportedly ranges between 8 and 17%.²⁸ It is difficult to determine the exact prevalence of iatrogenic injury during laparoscopy because certain complications are not usually reported,²⁹ for obvious reasons.

Vessel injuries attributable to trocars are usually more obvious and catastrophic than injuries related to Veress needle insertion. Transmural vessel injury related to trocars is the rule rather than the exception.³⁰ When recognized, the trocar and cannula should be left in place and a conventional vascular repair performed. An expanding retroperitoneal hematoma, hemodynamic instability in the face of active bleeding, and active intra-abdominal hemorrhage that cannot be managed laparoscopically are all indications for conversion to laparotomy and exploration or vascular repair. Trocar-related major vascular injuries reported to the Food and Drug Administration (FDA) by the medical device industry between 1993 and 1996 were reviewed.³¹ Of the 408 injuries reported, 26 resulted in death and 87% occurred despite the use of trocars with safety shields. The most common site of injury was the aorta (23%), followed by the vena cava (15%). A more recent review of FDA reports focused on two optical access devices that purported to provide a degree of safety by allowing the operator to insert a clear but sharp trocar with a laparoscope positioned within it.³² In that report, 37 major vascular injuries of the aorta, vena cava, and iliac vessels were described, and four deaths were described in relation to vascular injury. These reports seem to validate the notion that safety shields, designed to protect vessels and viscera, do not provide such protection and justify the FDA decision to forbid the term in product labeling. From these reports, it also seems as if in some cases, the diagnosis of major vascular injury may be delayed, usually because of retroperitoneal bleeding, with symptoms manifesting in the recovery room.

Abdominal wall vascular complications are typically managed with devices designed to facilitate fascial closure of laparoscopic port sites (suture passers) when possible. It is important to visualize all trocar sites after each trocar is removed at the end of the case to minimize the possibility that an abdominal wall vessel has been injured but has not yet bled because of tamponade by the trocar itself.³³

Visceral Injury

Although studies have suggested that the open technique of initial trocar placement may be associated with a lower incidence of major vascular injuries, the same cannot be said

for visceral injuries.³⁴ The incidence of this complication is about 0.05% of all open access procedures.³⁵ The main difference between bowel injuries occurring during the open technique compared with the closed technique is that with the open procedure, it is more likely that the injury will be immediately obvious and repaired without delay. Veress needle injuries to the large and small bowel may be associated with a higher incidence of peritonitis and other complications than injuries to the stomach, which can often be managed conservatively.¹⁰ If it is suspected that the Veress needle has penetrated the bowel, the needle should be left in place and a second needle placed in another location. Once abdominal access is established, the location of the needle should be ascertained, and repair of any injuries should proceed as appropriate related to the nature of the injury.

Physiology of Pneumoperitoneum

The introduction and widespread acceptance of laparoscopy have created new challenges for anesthesia providers. Laparoscopic surgery and carbon dioxide (CO₂) insufflation have introduced unique management concerns and physiologic consequences for patients. When one considers the fact that many patients undergoing laparoscopic surgery are likely to be sent home shortly following the procedure, it becomes important for surgeons to understand these physiologic consequences and potential ramifications as well.

CARDIOVASCULAR EFFECTS

Intraoperative Position

Patient position is important during laparoscopic surgery to help facilitate visualization of the operative field. For upper abdominal surgery, the reverse Trendelenburg position (head up) can enhance exposure of the operative field. The extreme reverse Trendelenburg position with the aid of a padded footboard has been advocated in bariatric surgery as a means of maximizing exposure. In lower abdominal and pelvic surgery, the Trendelenburg position (head down) enhances operative exposure. It has been demonstrated that intra-abdominal volume varies as a patient's position changes.³⁶ When compared with the supine position in laparoscopic surgery, the Trendelenburg position is associated with increased intra-abdominal volume, and the reverse Trendelenburg position is associated with decreased volume. Decreased intra-abdominal volume may correlate with impaired visualization for the surgeon, possibly extending the operative time and impacting the ultimate outcome in other ways (e.g., increasing doses of muscle relaxation in a quest to see better and poorly visualized anatomy).

An increase in intra-abdominal pressure up to 12 to 15 mm Hg decreases venous return, which results in reduced preload and cardiac index (CI), without adequate intravascular volume loading. The common belief is that changes in body position, especially the reverse Trendelenburg position, intensify these negative effects of pneumoperitoneum, whereas the Trendelenburg position has a positive effect on venous return and hence cardiac output (CO). These physiologic effects are likely minimized in euvoletic patients.³⁷ Invasive hemodynamic monitoring can be used to determine the hemodynamic consequences of laparoscopic surgery in healthy

volunteers. Joris and colleagues determined that CO decreased by as much as 50% of the preoperative value after the beginning of the laparoscopy and that systemic vascular resistance (SVR) increased accordingly.³⁸ Hirvonen and colleagues conducted a similar study but took measures to prevent the peripheral pooling of blood, which can happen with the reverse Trendelenburg position, and increased intra-abdominal pressure related to pneumoperitoneum.³⁹ Before laparoscopy, the patients received an intravenous infusion of colloid solution if cardiac filling pressures were low and their legs were wrapped from toes to groin with elastic bandages. A 20% decrease in CO and a 30% decrease in stroke volume (SV) were observed during laparoscopic cholecystectomy in healthy subjects when compared with preoperative values. With the change in position from the supine to the reverse Trendelenburg position in awake and anesthetized patients, the CI, stroke index (SI), central venous pressure (CVP), and pulmonary capillary wedge pressure (PCWP) decreased and SVR increased.

In robotic prostatectomy, where patients are placed in a steep (40°) Trendelenburg position for several hours, it has been demonstrated that mean arterial pressure (MAP) and CVP increased significantly.⁴⁰ First, the observed increase in pressure is the result of increased hydrostatic pressure at the external auditory meatus caused by the tilting of the table. In addition, because MAP increased by a greater absolute amount than CVP, at least part of the observed increase in MAP must also be caused by increased CO, SVR, or both. Several additional investigators have demonstrated that placing the patient in the Trendelenburg position is associated with an increase in the CVP, with the CO remaining the same or increasing.^{41,42} The induction of pneumoperitoneum has been reported to reduce, elevate, and have no effect on CO in different reports.^{37,43,44} Position as an independent factor on the hemodynamic profile is much less studied than the hemodynamic consequences of pneumoperitoneum.

Pneumoperitoneum

Insufflation of the peritoneal cavity with CO₂ during laparoscopic surgery leads to an increase in the intra-abdominal pressure. Drawing conclusions on the effect of pneumoperitoneum alone on hemodynamic function is difficult as a result of the confounding variables of study methodology, anesthesia, position of the patient, surgical stimulus, and condition of the patient. The effects of pneumoperitoneum on cardiac physiology have been found to depend on the magnitude of the pressure increase, intravascular volume, and underlying cardiovascular status of the patient. The creation of pneumoperitoneum to an intra-abdominal pressure of less than 20 mm Hg in the supine position is generally associated with an increase in the MAP and SVR, although the clinical impacts of these changes are determined by a variety of patient-specific factors.^{45,46} Older animal studies have looked at the impact of pneumoperitoneum in relation to intravascular volume status. It has been demonstrated that at very high intra-abdominal pressures in a dog model, CO decreased by 53% in hypovolemic dogs and by 15% in normovolemic dogs but increased by 50% in hypervolemic dogs.^{47,48} At low and normal right atrial pressures (low and normal volume status), the inferior vena cava (IVC) is compressed and collapses, causing a decrease in venous return. In hypovolemic dogs,

the poor cardiac performance is postulated to be further compounded by the increase in total peripheral resistance related to the compression of the splanchnic arterioles by the increased intra-abdominal pressure. On the other hand, at high right atrial pressures (hypervolemic status), the venous return to the heart is actually augmented as the IVC resists compression. CO in these animals is likely increased related to the Starling mechanism. In humans, the effects of varying pneumoperitoneum-induced changes in intra-abdominal pressure have been studied at much lower pressures.^{49,50} Invasive monitoring and echocardiography were used to evaluate the hemodynamic changes as the intra-abdominal pressure increased from low (7 mm Hg) to higher (15 mm Hg) in healthy patients undergoing elective laparoscopic cholecystectomy. At low insufflation and intra-abdominal pressures, an overall mild increase in MAP, SV, and CO was observed. At 15 mm Hg insufflation pressure, the SV and CO were observed to decrease to a similar degree. There are few published data on the effect of higher insufflation pressures in humans during laparoscopy. In 100 healthy women undergoing elective gynecologic procedures, initial insufflation to an intra-abdominal pressure of 30 mm Hg was attained prior to insertion of the primary trocar. Heart rate, blood pressure, and pulmonary compliance were measured at 15 versus 30 mm Hg. A significant increase in MAP and a decrease in pulmonary compliance were observed at 30 mm Hg compared with 15 mm Hg.⁵¹ Unfortunately, CO and other hemodynamic parameters were not evaluated.

Bradyarrhythmias have been reported to occur with the induction of pneumoperitoneum. These arrhythmias are most likely related to the vagal stimulation induced by peritoneal stretching on insufflation.⁵² In one recent study of patients undergoing laparoscopic urologic surgery, 28% of patients developed bradycardia perioperatively compared with 0% of patients randomly assigned to a treatment group to receive a dose of atropine prior to pneumoperitoneum induction.⁵³ Treatment of bradycardia on induction of pneumoperitoneum consists of immediate cessation of surgical stimulation, abdominal deflation, and the administration of anticholinergic drugs such as glycopyrrolate or atropine.

Carbon Dioxide

CO₂ is the preferred gas for abdominal insufflation in laparoscopy as a result of its lack of flammability, solubility, and ready availability. CO₂ insufflation results in diffusion of CO₂ into the blood and an increase in its elimination through the lungs. The CO₂ load is greatest during extraperitoneal insufflation (e.g., preperitoneal inguinal hernia repair) compared with intraperitoneal insufflation.⁵⁴ The cardiovascular effects of hypercarbia seen during laparoscopic procedures are not as significant when compared with the effects of patient position and pneumoperitoneum provided that the arterial carbon dioxide tension (Paco₂) is kept below 50 torr by controlled ventilation (increased ventilation to increase CO₂ exchange and decrease Paco₂). Hypercarbia has effects on the myocardium (myocardial irritability with transient arrhythmias, increased contractility), central nervous system (increased sympathetic tone), and periphery (vasodilation with a decrease in the SVR). The net effect is the negligible hemodynamic consequences of hypercarbia.⁵⁵ Studies comparing CO₂ pneumoperitoneum to pneumoperitoneum created with

alternative gases such as nitric oxide and helium have demonstrated that the hemodynamic effects are independent of the type of gas insufflated.⁵⁶

CO₂ embolism is a potentially fatal complication caused by the insufflation of CO₂ directly into the circulation. CO₂ embolism occurs most frequently on the induction of pneumoperitoneum but can occur at any point in the operation.⁵⁷ Certain procedures, such as laparoscopic hepatectomy, are very commonly associated with small CO₂ gas embolisms that are usually subclinical, although clinically significant CO₂ embolism is still a major concern in these cases.⁵⁸ Cardiovascular collapse can occur rapidly with a large CO₂ embolism. Gas obstructs the right ventricular outflow tract, resulting in cyanosis, increased venous pressure, ventricular arrhythmias, and a decrease in the end-tidal carbon dioxide tension (P_{CO₂}). Immediate recognition of the problem is essential. Treatment consists of the immediate cessation of insufflation, positioning the patient in the head-down left lateral position, hyperventilation, and even aspiration of gas from the right atrium through a central venous catheter.

RESPIRATORY EFFECTS

The respiratory effects of laparoscopic surgery include those of pneumoperitoneum and positioning and are superimposed on the effects caused by the anesthetic itself. Lung volumes and compliance are decreased during laparoscopic surgery.

Effect of Pneumoperitoneum

The increase in intra-abdominal pressure caused by pneumoperitoneum also affects the pulmonary system by impeding diaphragmatic movement, leading to a decrease in the functional residual capacity (FRC) of the lung. Compliance is also decreased, mostly as a result of a cephalad displacement of the diaphragm and the chest wall. This disturbance in compliance is immediately reversible on abdominal deflation.⁵⁹ Airway pressures increase during CO₂ pneumoperitoneum because of decreased compliance and the need to increase minute ventilation to excrete the increased CO₂ load absorbed from the peritoneal cavity.

Hasukic and colleagues measured pulmonary function tests in postoperative patients who underwent laparoscopic cholecystectomy.⁶⁰ Pulmonary function tests demonstrated a decrease in forced expiratory volume in 1 second (FEV₁) and forced vital capacity (FVC). In spite of these documented effects of pneumoperitoneum on pulmonary function, studies have shown that the pulmonary status of patients after a laparoscopic procedure is actually less detrimentally affected than when compared with the open procedure.⁶¹

Oxygenation

Increasing pneumoperitoneum also causes an increase in alveolar dead space, leading to potential hypoxemia.⁶² This leads to ventilator-perfusion mismatching and intrapulmonary shunting. The risk of hypoxemia is counteracted by controlled mechanical ventilation during laparoscopic surgery with increased tidal volumes and the addition of positive end-expiratory pressure (PEEP).⁴⁰

Carbon Dioxide Absorption and Excretion

CO₂ is the most common gas used to obtain pneumoperitoneum during laparoscopic surgery. It is absorbed into the

bloodstream, where it is finally excreted by the lungs. Most of the CO₂ combines with water found in the red blood cells to form carbonic acid. Carbonic acid further breaks down into hydrogen, which is carried by hemoglobin, and bicarbonate, which diffuses into the plasma. A small amount of CO₂ does get dissolved directly in the bloodstream and is transported to the lungs for excretion.⁶³ Subcutaneous emphysema is a frequent occurrence and is commonly caused by leakage around an abdominal insufflating port. Extensive subcutaneous emphysema can be associated with significant respiratory acidosis, necessitating prolonged postoperative ventilation.⁶⁴

PAIN AFTER LAPAROSCOPIC SURGERY

Laparoscopic surgery has been shown to cause less postoperative pain when compared with the equivalent open technique for many operations. Some examples of common general surgery procedures where laparoscopic surgery has been shown to reduce postoperative pain include cholecystectomy, hemicolectomy, appendectomy, and inguinal hernia repair.^{65–67} In addition to incisional and visceral pain, laparoscopic surgery has been associated with shoulder tip pain. This referred pain is thought to be caused by the increased intra-abdominal pressure caused by the laparoscopic gas, resulting in diaphragmatic stretching and phrenic nerve irritation. As a result, shoulder tip pain is unique to laparoscopy and usually dissipates in 1 to 3 days as the CO₂ is absorbed into the systemic circulation. One method to reduce shoulder tip pain is by employing a lower pressure during the procedure; however, this can reduce the size of the surgical field.⁶⁸ Other techniques, such as intraperitoneal irrigation with local anesthesia, have shown promising results.⁶⁹

NAUSEA AND VOMITING AFTER LAPAROSCOPIC SURGERY

A common complaint by patients who have undergone a laparoscopic procedure is postoperative nausea and vomiting (PONV). This can be seen in as many as 40 to 75% of patients and can delay discharge of patients, especially during outpatient surgery.⁷⁰ Patients rank vomiting as the number one complication of surgery they want to avoid and rank nausea in the top five. When patients are given the option of allocating \$100 out of pocket to the prevention of postoperative complications, they choose to allocate approximately \$30 for the prevention of PONV.⁷¹ The etiology of PONV from a purely surgical standpoint (not taking into account the effects of anesthetic gas) is likely attributable to a combination of peritoneal gas insufflation and bowel manipulation.⁷² Postoperative opioids, female sex, history of motion sickness, history of migraine, duration of the operation, and a previous history of PONV have all been demonstrated in a predictive model as significant independent variables with marked association with PONV.⁷³ The newest guidelines delineated in the 2008 consensus guidelines for the management of PONV suggest that the clinical team should evaluate the patient's risk for PONV, reduce baseline risk factors for PONV, evaluate the patient's preferences, and determine the cost-effectiveness of antiemetic prophylaxis before deciding to administer PONV prophylaxis to the patient.⁷⁴ Other than identifying patients at the greatest risk for PONV, guidelines include reducing baseline risk factors (avoid general anesthesia when possible, use propofol for induction and maintenance of anesthesia, avoid nitrous oxide and volatile anesthetics, minimize opioids and

neostigmine, and maintain adequate hydration) and administering antiemetics prophylactically in moderate- and high-risk patients in the appropriate dose and at the appropriate time. A recently published economic analysis of routine prophylaxis of PONV in all surgical patients determined that the study site hospital's net profit increases linearly with increased

PONV prophylaxis administration. Economic analysis showed that PONV prophylaxis was economically beneficial for the hospital when weighed against the expense generated by treating patients returning to the hospital with PONV.⁷⁵

23 TECHNICAL ASPECTS OF LAPAROSCOPIC SURGERY

Haggi Mazeh, MD, Charlotte Rabl, MD, and Guilherme M. Campos, MD, FACS

Laparoscopic surgery is one of the most important technical advancements in general surgery in the last century. From its initial pioneering application for appendectomy and cholecystectomy in the late 1980s and early 1990,¹ laparoscopic surgery has grown to be routinely used in almost all known surgical procedures. Its proper use is associated with many benefits to both patients and health care systems. Documented advantages over open techniques include faster patient recovery, shorter hospital stay, decreased pain and analgesic requirements, and faster return to work.²⁻⁵ For many procedures, reduced rates of surgical complications have been documented, such as postoperative ileus, surgical site infection, and pulmonary complications.⁶⁻¹² Other long-term benefits are lower incidence of postoperative ventral hernias and intra-abdominal adhesions, as well as better cosmetic results.¹³⁻¹⁷

During its first years, laparoscopic surgery employed a combination of simple diagnostic laparoscopic instruments with endoscopic graspers and laparoscopic biopsy forceps used for diagnostic laparoscopy. For many decades, diagnostic laparoscopy had been used to evaluate pelvic diseases, abdominal pain, liver diseases and to perform liver biopsies.¹⁸ In contrast, laparoscopic surgery requires skills, techniques, facilities, and equipment far beyond those required for diagnostic laparoscopies. Improvement in instruments and the understanding of the multiple technical details that are necessary to safely perform laparoscopic surgery were fundamental to the rapid growth that followed the introduction of the technique. The purpose of this chapter is to highlight the technical aspects of laparoscopic surgery, operating room and patient preparation, proper choice and use of selected instruments, and training to acquire basic and advanced technical skills.

Operating Room Setup and Patient and Surgery Team Positioning

Until recently, most laparoscopic procedures were performed in operating rooms that were originally designated for traditional open surgery. With the growth of advanced laparoscopic technology, larger suites specially designed for laparoscopic surgery are recommended to facilitate patient, anesthesia, and surgical team positioning and accommodate all ancillary equipment that may be needed.

OPERATING TABLE LOCATION AND REQUIREMENTS

The operating table should be located at the center of the room. It should be positioned far enough from the doors and allow adequate room for the anesthesia equipment and personnel to have access to fluoroscopic and other imaging and endoscopy equipment. The operating table should enable

intraoperative access for fluoroscopy and endoscopy equipment. It should also be versatile to allow safe controlled movement of the patient in all directions, as is commonly required during advanced laparoscopic procedures. Access to the upper abdomen or pelvis is greatly facilitated by placing the patient in a reverse Trendelenburg or Trendelenburg position. Mechanical support and appropriate padding are recommended to prevent patients from sliding, as well as enabling the variety of patient positions that are necessary during most laparoscopic procedures. Lastly, laparoscopic instruments are usually longer than handheld instruments used in open surgery; therefore, the best operating table position in laparoscopic cases is considerably lower. In larger or obese patients, inability to lower the operating table may result in inappropriate surgeon positioning with prolonged abduction of the shoulders during the procedure. Adding a standing platform allows proper surgeon positioning.

SURROUNDING THE OPERATING TABLE

The location of the laparoscopic tower and the monitors varies according to the planned procedure; however, video monitors should be placed for convenient viewing by both the surgeon and the assistant. A minimum of two video monitors is suggested, especially in cases where the surgeon and the assistant(s) stand on different sides of the operating table. It has been demonstrated that the optimal height of the monitor is no higher than the surgeon's eye level.^{19,20} The preferred position of the laparoscopic tower is on the side opposite the doors to the operating room so that heavy instruments can be wheeled in when needed.

Numerous hospitals around the world are undertaking the conversion of traditional operating rooms into state-of-the-art laparoscopic suites. Such renovations require careful planning.²¹ In modern laparoscopic operating rooms, the heavy-wheeled towers are replaced by overhead ceiling-mounted booms that can be positioned as needed. All laparoscopic control equipment should be mounted on the booms. This includes light source, CO₂ insufflators, camera controls, and processors [see *Figure 1*]. Moreover, cautery and ultrasonic dissector units, as well as suction and irrigation units, are mounted on the booms to maintain a cable-free floor and avoid potential obstacles that may compromise both the patient's and the surgical team's safety. It is advisable to establish a control desk for the circulating nurse, allowing full control over all lights, monitors, and equipment on the booms. Camera processors and monitors should contain multiple input and output sources all controlled through a video router. This will allow multimedia communication, which may be required in certain procedures. A short and not all-inclusive list of possible media communication includes

Figure 1 Schematic representation of a ceiling-mounted articulated boom for laparoscopic surgery with high-definition monitors. Reproduced with permission from Stryker Instruments, Kalamazoo, MI.

laparoscopic camera, fluoroscopy, endoscopy, ultrasonography, anesthesia monitor, digital video recording, outside hospital video receiver, and transmitter.

Wireless high-definition video has also been introduced to the operating room recently, which has helped improve the workflow in the operating room, eliminate clutter, and streamline the continuum of care. Wireless technology will also help enable the electronic transfer of data to centralized repositories such as electronic medical records systems or remote and even overseas training facilities.

PATIENT POSITIONING

The exact patient position varies from one procedure to another and among different surgeons [see Table 1]. For example, for a simple laparoscopic cholecystectomy, most surgeons will place the patient supine and stand on the left side. However, some surgeons will prefer the split leg position and will place themselves between the patient's legs. All common patient positions apply for different laparoscopic surgeries, although some aspects need to be highlighted. During laparoscopy, the position of the operating table is often rotated to extremes to enhance gravity forces that act mainly on the bowel. For such angles, restraints, supports, and proper patient padding are mandatory. Liberal use of anchoring devices, leg and arm support, straps, and a foot board is recommended. It should be routine to move the patient into the desired position(s) that will be used during the proposed procedure before patient draping. This ensures that the patient will not slide or have inappropriate pressure applied to extremities or other body parts during the procedure itself. The preferred position of the patients' hands is alongside the patient's body, allowing maximal range and freedom of movement for both the surgeon and the assistant.

It is still controversial as to whether laparoscopic surgery alters the risk of a thromboembolic event. Two factors may lead to an increase in the risk of a thromboembolic event: longer operating times in selected cases and reduced venous return from the inferior extremities as a result of pneumoperitoneum and reverse Trendelenburg position. Conversely,

Table 1 Different Patient Positions Used for Laparoscopic Surgical Procedures	
Procedure	Possible Patient Positions
Esophagectomy	Supine, split leg, left/right lateral decubitus
Paraesophageal hernia Nissen fundoplication	Supine, split leg
Splenectomy	Supine, split leg
Gastrectomy	Supine, split leg
Bariatric surgery Adjustable gastric banding Sleeve gastrectomy Roux-en-Y gastric bypass	Supine, split leg
Cholecystectomy, liver resection	Supine, split leg
Adrenalectomy	Lateral decubitus
Appendectomy	Supine
Adhesiolysis	Supine
Hernia Inguinal/umbilical/ventral	Supine
Abdominal colectomy	Supine
Rectal surgery Low anterior resection Abdominoperineal resection Total proctocolectomy	Lithotomy

laparoscopic surgery seems to be associated with less operative trauma and inflammatory response,²² earlier ability to ambulate, decreased pain, and shorter hospital stays, all of which are thought to decrease the risk of a thromboembolic event. Intraoperative intermittent pressure compressions are recommended for all prolonged laparoscopic procedures.²³ Three randomized clinical trials have evaluated the need for chemical thromboprophylaxis in laparoscopic surgery; the results suggest that use of chemical thromboprophylaxis should be based on assessment of patients' risk factors and prolonged cases.^{24–27} Current guidelines by the American College of Chest Physicians do not support the routine use of chemical thromboprophylaxis for patients who do not have additional thromboembolic risk factors and recommend early and frequent ambulation for patients undergoing entirely laparoscopic procedures.²⁸

SURGEON POSITIONING

The position of the surgeon varies according to the planned procedure and the surgeon's preference. The surgeon should plan where to place the assistant and the camera holder, and if rotation of positions is necessary, it is important to place the operating table surroundings in a reasonable fashion.

Alignment is key to both the surgeon's convenience and optimal eye-hand coordination. The surgeon's eye, hand, camera, operative field, and monitor ought to be aligned in one line.

In 2009, van Det and colleagues²⁰ summarized guidelines for optimal laparoscopic surgery suites:

Monitor position:

- Straight ahead of each person in line with the forearm-instrument motor axis

- No higher than the surgeon's eye level (preferred 15° downward)
- Distance according to monitor size

Patient position:

- Ensure that arms or legs do not interfere with the surgeon's movements
- Enable surgeon's alignment with the operating field

Equipment position:

- Does not disrupt the eye-hand-target axis
- No view blockage for the surgeon, assistants, and nurses
- Allows free axis to the patient and surgeon and assistant position rotation

Laparoscope and Instruments

The essential equipment needed to perform laparoscopic surgery is the laparoscope, light source, camera head, video system, and CO₂ insufflation device.

LAPAROSCOPE

The laparoscope is obviously required to perform laparoscopic surgery. It has evolved over the past two decades from a handheld to the eye instrument [see Figure 2] to the articulating flexible 5 mm scopes [see Figure 3a], three-dimensional video coding, higher resolution and higher definition cameras and monitors, and split-screen monitors that can combine sonograms, CT scans, and real-time endoscopy images.

Endoscopes are usually attached to a camera—either built-in or separate. Another important component is the light source that connects to the endoscope through a light cable. All three components deliver the image to a processor that projects the image on the monitor, and the combination of all elements determines final image quality. Most light sources have a brightness control feature, but the features of the camera differ by manufacturer. Zoom, focus, and white balance are principal actions present in virtually all cameras [see Figure 3b].

The most commonly used endoscope is a rigid apparatus with a set of lens and fiberoptic bundles that project the image to the camera. The diameters of endoscopes range from 2 to 10 mm. Endoscopes are traditionally divided into angled and nonangled scopes. A nonangled (0°) endoscope has a flat end and offers the surgeon only a straight-ahead look. This obviously limits the ability to properly view the entire surgical field. To overcome this limitation, angled endoscopes were produced available at 30 or 45°. The angled scope may rotate 360° and thus offer better viewing. The use of angled endoscopes has been demonstrated to decrease the incidence of complications in laparoscopic cholecystectomies.^{29,30} The new generation of endoscopes has mobile tips, which can flex, and employ “chip-in-the-tip” technology—video chips in the distal end of the endoscope, which, on top of magnification, offers the surgeon a view around obstructing structures.

The combination of the endoscope and the camera projects the image to the monitor. Major progress has been made in this technology. Analogue images transferred via S video cable are now in the process of being replaced by digital and high-definition cameras and monitors. High-definition cameras offer benefits for surgeons performing operations

Figure 2 Blueprints and photographs of the first endoscope. Introduced by Phillip Bozzini of Frankfurt, Germany. Despite accurate blueprints and a fine design (background), his work was repudiated by the Vienna School of Medicine. His early demise at age 36 years hampered further progress in the development of endoscopy until the work of Pierre Segalas of Paris, France, and Adulph Kussmaul of Frieberg, Germany. Reproduced with permission from Arch Surg 2004;139(10): 1110–1126 Figure 1. Copyright © 2004 American Medical Association. All rights reserved.

and those viewing a procedure at another location. In high-definition systems, the surgeon may see better even when there is blood on the field as a result of reduced red color saturation. With the new cameras, surgeons can have an optimal view of the surgical field, even when using smaller diameter scopes. High definition also provides a wide-angle view,

Figure 3 Articulated 5 mm scope (a) and high-definition camera head (b). With permission from Stryker Instruments, Kalamazoo, MI.

which allows surgeons to more quickly see instruments moving in and out of the surgical field, and depth of field is improved. Lastly, high-definition systems allow the use of a two-dimensional image but augment identification of visual clues used to judge depth of field. It has been shown in surgical training laboratories that high-definition systems improve certain functions, such as tying knots and suturing, and reduce “sword fighting” or moving instruments around before getting to the target.^{31–33}

One frustrating component of laparoscopic surgery is the fogging of the scope, which in turn forces the surgeon to stop the procedure until a clear image is reobtained. The fog is created because of the temperature difference between the endoscope and the abdominal cavity. For this reason, endoscopes are warmed in hot water before being introduced into the abdomen. Several antifog solutions are commercially available. These are hydrophilic solutions, and water vapor accumulates on the glass as a thin layer of water, preventing fog. Some new technology cameras include an integrated antifog pump that achieves longer periods of clear visualization.

INSTRUMENTS

Incredible progress has been made over the past two decades in instrumental development for laparoscopic procedures. This development was possible because of the full and intense cooperation between surgeons and industry. Surgeons dictated the need and in many instances were involved in the actual development of specific instruments. Instruments are inserted through the trocars, and the range of movements is limited by trocar mobility. Most laparoscopic instruments include two basic movement-adjustment abilities. First, all instruments can be pushed in and out of the trocar and the abdominal cavity. Second, instruments can be rotated 360° either by rotating the hand that holds the instrument or by manually turning the rotating knob. Some devices are equipped with an articulating feature that enables angularity of the instrument’s end. These limited movements and the diminished tactile sensation were the basis for continuous and ongoing device development. The list of available instruments and devices and their description are beyond the scope of this chapter. A few examples of the most common are depicted in Figure 4: graspers, dissectors, scissors, and other basic surgical instruments are available in different sizes (3 to 10 mm) and lengths, but their mechanism of action and utility are similar to those for open surgery. Below we discuss in detail hemostatic devices and endoscopic staplers and the importance of ergonomics.

Hemostatic Devices

The importance of preventing and controlling intraoperative bleeding is common to all surgical procedures. Bleeding not only prevents visualization of the anatomy; also, the dark color of the blood absorbs the light and decreases image quality. In comparison with open surgery, knot tying a vessel laparoscopically is time consuming, and the ability to control massive bleeding is limited. Hence, bleeding has traditionally been the most common cause of conversion to open surgery,³⁴ and hemostatic devices therefore play an important role in laparoscopic surgery.

Figure 4 Assorted laparoscopic instruments: traumatic and atraumatic graspers, hook and spatula cautery, suction tip, scissor, and right angle dissector.

Monopolar devices These devices use a simple monopolar current and are similar to open monopolar cautery. Two unique instruments are available: the spatula electrode, with a flat end, is primarily used to dissect the gallbladder off its liver bed; the hook electrode can apply cautery and pose traction at the same time. Many dissecting and cutting instruments can also be connected to monopolar cautery and assist in achieving bloodless surgery. The exposed electrode tip must be visible whenever the unit is operating, and the tissue has to be placed in tension to achieve cutting. The minimal current and power settings needed to achieve desired results should be used, and it is generally recommended to avoid using over 30 watts of power. If the current is on for long periods, the chance of remote-site electrical injury or burn is increased.

Bipolar devices Bipolar devices induce hemostasis by transmission of current between the coupled plates of the tip. They achieve greater hemostasis than monopolar devices while minimizing thermal injury to surrounding tissues. A popular and effective electrothermal bipolar vessel sealing system is the Ligasure Vessel Sealing System (LigaSure, Covidien Energy-based Devices, Boulder, CO), which is available in both 5 and 10 mm sizes [see Figure 5, a and b]. It achieves hemostasis in small, medium, and large arteries and has been shown in a recent meta-analysis to reduce operative time by 25% without an increased risk of bleeding or other complications when compared with conventional mechanical hemostatic methods.³⁵

Both monopolar and bipolar devices generate smoke that may interfere with laparoscopic visualization. However, visualization is not the only issue. The National Institute for Occupational Safety and Health (NIOSH) has issued a warning regarding the possible health effects of exposure to surgical smoke plumes.³⁶ Although studied only in laboratory simulations, smoke evacuation systems are recommended.

Figure 5 (a) Ten and (b) 5 mm LigaSure and (c) 5 mm harmonic scalpel.

Such systems are easily connected to one of the trocars to facilitate smoke evacuation.

Ultrasonic Shears

The introduction of ultrasonic shears (harmonic scalpel, Ethicon Endo-Surgery, Cincinnati, OH) into clinical practice in 1991 greatly advanced the practice of laparoscopic surgery [see Figure 5c]. Before that time, the requirement that all vessels be dissected, identified, and ligated or clipped resulted in longer operative time and increased bleeding. Similar to bipolar devices, harmonic shears enable the surgeon to grasp tissue and provide energy to that tissue alone. One blade of the shears oscillates at 55,000 cycles per second, generating localized heat of 50 to 100°C. This leads to denaturation of vascular proteins and focal coagulation. The lateral thermal spread is limited to 2 mm of surrounding tissue, making the device an efficient tool for both bowel and solid-organ laparoscopic surgery. Harmonic shears generate smoke to a lesser degree than electric current devices. Two important limitations must be kept in mind while using the harmonic shears. First, the oscillating blade remains hot for several seconds, during which avoidance of contact with delicate tissue (e.g., bowel) is advised. Second, the utility of harmonic shears to seal major vessels is limited. Named vessels are better transected after ligation using staples or clips.

Few studies have directly compared the use of ultrasonic energy methods (harmonic scalpel) with a electrothermal bipolar vascular system (LigaSure) in adrenal, hepatic, and colorectal surgery, but the design of these studies did not permit definitive conclusions.^{35,37}

Clips

Clips are used in a manner similar to that of open surgery. They are most efficient for sealing blood vessels or any other

luminal structure, such as ducts or ureter. The mechanical seal that they provide allows them to be used close to bowel wall or other delicate tissue. Clips are available in different sizes, materials, and lock mechanisms. Partial compression of the clip applicator handle closes the distal end of the tip first. This prevents tissue release and allows the clip applicator to slide along the structure to be clipped. Full compression of the handle will close the clip completely. Nearly all disposable laparoscopic clip applicators have multifire capabilities and 360° rotation, whereas only some clip applicators can articulate.

Loop Ligature (Endoloop)

The endoloop consists of a long preformed ligature inserted into a plastic tube [see Figure 6]. The plastic tube is narrow at one end and scored on the other. The suture protrudes from the narrow end and is formed in a ligature loop with a knot, which becomes secure after the device is activated.

Endoloops are simple to use and are used to place secure knots over thicker structures that could not be securely clipped (e.g., appendix's base, thick cystic duct). The surgeon should insert the endoloop and place the loop proximal to the structure to be ligated. At this point, a grasping instrument is placed through the loop and grasps the desired structure. The loop is then slid over the instrument and onto the structure and secured by pushing down the knot with the applicator using simple traction. Once tightened, the scored end is cut, the plastic tube is removed, and the ligature is divided close to the knot.

Other Hemostatic Devices

The field of hemostasis technology is constantly exposed to new innovations as well as laparoscopic application of open surgery techniques. Lasers are used to induce coagulation on the raw surface of solid organs such as the spleen and liver and in gynecologic surgery. Three types of lasers are most commonly used: CO₂, argon, and Nd:YAG. The CO₂ laser is the most precise laser but has limited coagulating ability. The argon laser has less precision but improved coagulating ability. The Nd:YAG laser has the best coagulation properties and the least amount of precision. The reaction of tissue to lasers varies according to wavelength and tissue characteristics. The most common complication is inadvertent laser burns, which account for 1.2% of all laparoscopic complications.³⁸

Fibrin sealing products (e.g., fibrin glue) provide insoluble fibrin matrix and are also used on raw surfaces, such as the liver, or on an oozing staple line.

STAPLERS

Suturing is the mainstay of tissue approximation during open surgery. However, as with open surgery, staplers are

Figure 6 Endoloop with a 2-0 polyglactin tie.

increasingly used for specific procedures. Laparoscopic staplers are similar to regular open surgery staplers and can have different lengths (30 to 60 mm) and staple heights, be linear or circular, and have two to three staplers rows. To overcome range of motion and angle limitations, the new-generation laparoscopic staplers articulate to allow proper placement of the stapler line. Before a staple line is applied, careful planning is mandatory. The surgeon should choose the stapler that is most suitable for the specific case: linear or circular, articulating or straight. Another consideration in linear staplers is the length of the staple line. Staple length varies from 30 to 60 mm, and the length selected should match tissue length. Multiple firings are needed in many situations. Another important consideration is the height of the staples. Height is usually represented by colors in the following order: gray, white, blue, gold, and green [see Table 2]. The number of staples per cartridge ranges from 44 to 88 and most cutting staplers leave a 2 to 4 mm undivided portion at the distal aspect of the staple line. Once the cartridge is selected, the stapler should be inserted through a large trocar (12 mm) that allows correct alignment with the designated tissue. At this point, it is important for the assistant to retract the tissue to achieve correct positioning. As in open surgery, it is crucial to confirm that no other tissues have been grasped by the stapler and to visualize the stapler end. Most staples allow a grasp-and-release mechanism to optimize tissue alignment. The upper jaw should be closed against the anvil and the staples deployed slowly to deliver steady and optimal compression on the tissues and create a uniform staple line. Once the firing trigger is deployed, the staple's wires in the cartilage are forced through the tissue and against the anvil to form staples. A correct staple line is one that is aligned, complete, and in form is similar to the letter B, with the points inverted throughout the tissue depth. Crossing staple lines are a weak point and should be avoided when possible. A newer technique has been introduced with the Tri-staple technology (Covidien Energy-based Devices). This technology seems to offer enhanced tissue compression; the taller outer row provides holding strength with reduced tissue stress, and the inner shorter row offers tighter closure and increased hemostasis.

Buttress additives to staplers are commonly used. Available buttressing includes bovine pericardium (Peri-Strips Dry, Bio-Vascular, Inc., St. Paul, MN), polytetrafluoroethylene

(Gore-Tex, W.I. Gore, Boulder, CO), bioabsorbable product (Seamguard, Gore & Associates, Inc., Flagstaff, AZ), and small intestinal submucosa (SIS, Cook, West Lafayette, IN). The literature is inconclusive regarding the actual added value of these products, but their use seems appropriate in selected patients.

Laparoscopic staple design continues to evolve. Both time and funds are invested by industry to constantly improve ergonomics and efficacy and reduce complication rates. Growing demand and industrial improvement ensure further innovations in the future.

RETRACTORS

Traction and countertraction of organs and tissues are mainstay features that allow proper visualization and safe performance of laparoscopic surgery. One simple and common example is the traction of the gallbladder during laparoscopic cholecystectomy. One instrument pushes the gallbladder dome above the liver, enabling a clear view and access to the hilum while simultaneously lifting the right liver lobe. The countertraction is achieved with another instrument that pulls on the Hartmann pouch and assists in identifying the correct dissection plane. Although most of the retraction is performed with different graspers, some specifically designated retractors are available especially for solid organs such as the liver.

Fan Retractors

Fan retractors are available from different manufacturers and may be inserted through 5 to 10 mm trocars. They are designed to retract the liver, the small bowel, or any other organ needed. Fan retractors may be straight or curved. They can articulate and be locked in position using a strong arm attached to the operating table.

Nathanson's Retractors

Nathanson's flex arm (Cook, Bloomington, IN) is a laparoscopic liver retractor that is designed for bariatric or general laparoscopic surgery [see Figure 7a]. It supports and retracts the liver in an evenly distributed fashion and connects to an external fixation device that is attached to the operating table. It is introduced through a small incision in the upper abdomen without the need for a trocar.

Snake Retractors

A flexible 5 mm laparoscopic flexible snake retractor (Genzyme Surgical Products, Tucker, GA) forms a loop that may support liver retraction [see Figure 7b]. The retractor is introduced into the peritoneal cavity in its straight, inactive form. Once inside the abdomen, the distal end is closed under laparoscopic visualization, and the retractor tip's final shape may be round or rectangular. The retractor also connects to an external fixation device that is attached to the operating table. Because of its atraumatic shape, the liver can be safely held clear of the operative site in this manner for extended periods of time.

External Retractors

External retractors such as the Buchwalter and Thompson retractors are used to apply external retraction of the abdominal wall for procedures involving the diaphragm or upper abdomen.

Table 2 Staple Heights and Colors

Color	Open Staple Height (mm)	Closed Staple Height (mm)
		
Gray	2.0	0.75
White	2.5	1.0
Blue	3.5	1.5
Gold	3.8	1.8
Green	4.1–4.8	2.0–2.2

Figure 7 Various sizes of the (a) 5 mm Nathanson's retractor and (b) the round Snake retractor.

Hand-Assisted Laparoscopic Surgery

Perhaps the most versatile retractor is the surgeon's own hand. Silicone ports allow insertion of a single hand through the port without compromising the pneumoperitoneum. Some surgeons advocate this technique as it allows palpation, retraction, exposure, and manipulation of organs and tissue.

ERGONOMICS

Ergonomics play an important role in laparoscopic surgery and include the laparoscope, the instruments, and the patient and surgeon positioning. The manipulation of the instruments through the trocars; the position of the surgeon's body, arms, and fingers; and the different angulations are different than in open surgery. With proper insufflation of the pneumoperitoneum, patient positioning, angled scopes and instruments, laparoscopic surgery allows easier access to almost all areas of the abdominal cavity than open surgery. However, the trocars used in laparoscopic surgery provide reduced direct access to body cavities, reduced degrees of freedom in some interventions, and indirect visualization of the surgical field through the video system.

Laparoscopy-related discomfort has been reported by 40 to 60% of laparoscopic surgeons, and large survey studies report an incidence of strain symptoms (often persistent) in 12 to 89%.^{39,40} This strain is caused by several factors, including trocar, patient, and surgeon positioning and instrument ergonomics and design, among others. Some products today can be personalized to meet specific surgeons' needs. Nevertheless, although surgeons have different hand sizes, surgical instruments are produced in a single size. Most laparoscopic dissection and grasping instruments include a 360° rotating knob that reduces wrist movement and stress. However, most instruments are designed for finger-thumb grasp, resulting in hand symptoms accounting for up to 50% of strain symptoms

reported. Some grasping instruments are equipped with a ratchet locking mechanism that alleviates the need for the surgeon to apply constant grasping force. Stapling devices are also a continuous source of ergonomic stress. Most stapler systems still require two hands to close and deploy the device. Most needle drivers do not rotate and thus force the surgeon to manipulate his or her wrist, arms, and body to achieve the desired angle. The introduction of single port surgery has driven the industry to develop instruments that rotate in more than one axis. Possibly, further improvement will decrease the related discomfort.

Robotic surgery provides better ergonomic design for instrument handling, enabling the surgeon to manipulate instruments with increased freedom of movement and reduced physical strain. However, robotic surgery has not been proved to be of greater benefit in most minimally invasive procedures, requires operating room setup time, provides no tactile feedback, and costs more.

Laparoscopic Suturing

Laparoscopic suturing is an essential task and should be mastered by every general surgeon. Existing state-of-the-art clips and staplers do not replace sutures and cannot be relied on to do so in all cases. Laparoscopic suturing is, however, one of the more challenging aspects of laparoscopic surgery. Laparoscopic instruments are long, restrict ease of movement, and have diminished tactile feedback. Furthermore, the instrument's motion is inverted inside the abdomen with a varying scaling effect—a phenomenon known as the fulcrum effect. The fulcrum is defined as the point or support on which a lever pivots. The body wall acts as a fulcrum for surgical equipment so that when the surgeon moves the instrument to the right, the working end of the instrument moves to the left on the monitor, and vice versa. Surgeons are also limited by the imaging process. The magnification requires a proportional adjustment of the movement, and although the actual work is performed in three dimensions, it is guided by two-dimensional images. Fortunately, laparoscopic suturing and knot tying skills can be acquired via dedicated practice using box or virtual simulators.

POSITIONING AND INSTRUMENTS

Trocar and Surgeon Positioning

Trocars and surgeon positioning may either impede or simplify laparoscopic suturing. Ideally, the needle driver should reach the tissue parallel to the line of incision to be approximated to enable a 90° angle between the needle and the tissue. The angle between the needle driver and the grasping hand should not exceed 60 to 90° with the endoscope placed between the two instruments. Ports inserted too close to each other may create "sword fighting" and obscure visualization by the camera. In contrast, ports placed at a wider angle will force the surgeon to suture in a position with limited range of motion and excessive stress.

Standard laparoscopic suturing requires at least two instruments, with one or more inserted through a 10 mm trocar to allow needle insertion. A skilled assistant may ensure proper visualization by paying attention to the correct distance and angle of the camera at every stage of the procedure. The

surgeon should be positioned to create an eye-hand-camera-tissue alignment. The height of the operating table should be adjusted to avoid excessive arm and elbow abduction.

Instruments

Suture Selection of suture material is no different from that for open surgery. Multifilament sutures with memory features may ease handling and tying. The optimal suture length depends on the planned suturing technique. When intracorporeal suturing is attempted, an 8 to 15 cm suture is recommended for a single knot and up to 20 cm for a continuous segment. For extracorporeal tying, a suture length of 60 to 90 cm is required.

Needles The two most commonly used types of needles are the curved needle and the ski needle. The curved needle is more difficult to position and load but offers a clear pass through the tissue with a proper hand turn. The ski needle is easy to position and load because of its straight end but is inferior to the curved needle as it is associated with more tissue damage.

Needle drivers and graspers A needle driver [see Figure 8a] must hold the needle firmly but enable intended needle manipulation. The handles are either spring or ratchet loaded, and the jaw surface is coated with diamond to ensure proper gripping of the needle. In most needle drivers, one jaw is fixed to allow easier needle handling. Most needle drivers are handheld as opposed to the thumb and finger technique. The assisting instrument should be able to grasp both needle and suture with a preferred smooth end to avoid the loop catching on the instrument's shaft.

Endo Stitch suturing device The Endo Stitch (U.S. Surgical Corp., Norwalk, CT) [see Figure 8b] is a suturing device that has two jaws with a straight needle and suture material attached to each other and preloaded. A designated needle and suture material is held in one jaw and can be passed to the other jaw by closing the handles and flipping the toggle

levers. This apparatus is inserted through a 10 mm trocar and alleviates the need for needle loading; it also offers relatively simple knot tying. The Endo Stitch offers different suture materials (silk, nylon, and polyester) at different sizes (4-0 to 0). The length of the suture varies from 18 to 120 cm. As the Endo Stitch uses a straight and robust needle, it does not replace the standard techniques and materials. The Endo Stitch should not be used on all tissues, for example, the common bile duct and the pancreatic duct. It should also not be used for oversewing friable suture lines and tissues and other instances where finer needles and suture materials are indicated; thus, it is imperative that the modern laparoscopic surgeon be prepared to choose and use the appropriate instruments according to their specific indications.

Extracorporeal knot tying and the knot pusher

Extracorporeal tying is preformed with the suture pulled out of the 10 to 12 mm trocar. Once the knot is manually formed, the knot pusher is used to slide the knot through the trocar and tighten it around the tissue. This can be performed fairly easily with minimal training and repeated as many times as needed. As mentioned above, extracorporeal tying requires longer sutures that reach the operative field and return out of the same port.

Needle loading Placing the needle in the correct position is a challenging step in laparoscopic suturing. The suture is grabbed at 2 to 5 mm from the needle and inserted into the abdomen through the 10 to 12 mm trocar. At this point, the needle is grasped by the assisting hand and is introduced to the needle driver at the correct position if possible. There are different techniques for adjusting the needle position. Such techniques involve slightly releasing the needle grasp and adjusting it using the assisting grasper by either pulling on the suture or pushing gently on the needle. Training and experience are pivotal to mastering these techniques.

Suturing and Tying

The passage of the needle through the tissue is similar to open surgery. Carefully planned trocar placement allows the needle to be passed perpendicular to the tissue. In more difficult cases, the assistant may help with proper tissue alignment. Knot tying may be performed intra- or extracorporeally. The intracorporeal basic square knot is the most popular one. It is tied in a manner similar to that of open instrumental tying. After the needle is passed through the tissue, the suture tail is kept short and placed near the knot to allow easy grasping. After a C shape (C loop) with the suture is created, one of the instruments is brought into the loop, and the suture is wrapped twice around it. The tail is grasped by the instrument, and the knot is then tightened around the tissue [see Figure 9]. This is repeated with half-knots as needed. Numerous tying techniques exist and are less popular. Two other knots are worth mentioning. The Dundee jumping knot is used to initiate a running suture. A double loop is formed externally and introduced through the trocar. Once the needle is passed through the tissue, it is then passed through the loops, and the knot can be tightened. The Aberdeen knot is used to complete a running suture. An initial loop is brought beneath the last throw. A second loop is passed through the initial loop and tightened. The tail of the suture is inserted through the second loop to clinch the knot. The assistant should keep tension on the suture and prevent gaps in the

Figure 8 (a) Five millimeter needle drivers and (b) 10 mm Endo Stitch.

Figure 9 Illustration of laparoscopic suturing (square knot). Courtesy of Peter Polewski. (a) After the needle is passed through the tissue a C loop shape with the suture is created, then one of the instruments is brought into the loop and the suture is wrapped twice around the instrument (b, c). The tail is grasped (d) and the knot is tightened (e, f).

suture line. Laparoscopic suturing and tying is a fundamental skill that should be acquired before undertaking advanced laparoscopic surgery.

Laparoscopic Training and Simulators

Performing laparoscopic surgery requires specific skills that differ from the ones required for open surgery and may be improved by extensive training. These skills include accurate eye-hand coordination, the ability to perform procedures in a three-dimensional operating field reflected in a two-dimensional image, and the fulcrum effect (an inversion of the instrument's motion, which in turn increases surgeons' disorientation), among others. Learning laparoscopic skills

in simulators before entering the operating room results in improved performance during laparoscopic surgery with shorter procedure times, possible better patient outcomes, and decreased complication rates.^{31,32,41–43}

Laparoscopic training and simulators are now available in most teaching hospitals in the United States, and emerging technology has improved laparoscopy simulators dramatically. Today, three different laparoscopic simulators are used for training purposes: traditional video box trainers, virtual reality, and augmented (hybrid) reality simulators. All three have been demonstrated to enhance laparoscopic skills with proper training. Organic simulators (humans or animal) are not discussed in detail in this chapter. Organic simulators are still used; however, the validity and fidelity of the advanced

simulators seem comparable or better than those of organic simulators, and in the long term, there is a possible cost benefit for the simulators.⁴⁴

VIDEO BOX TRAINERS

Video box trainers were first introduced in the early 1990s as laparoscopic surgery gained acceptance. Although the technology has evolved, the basic principles of box trainers have remained constant. Today, video box trainers include a box, a positioned camera that reflects the image onto a monitor, and at least two trocars for instrument insertion. Different tasks may be performed using the box simulator, ranging from simple object grasping to complex suturing. Advantages of video box trainers include a relatively inexpensive and highly versatile device that enables the training on animal parts as well as synthetic inanimate models. The tactile perception is ideal for both the instruments and the tissues at hand. The obvious disadvantage is that box trainers do not offer the degree of fidelity possible in computer-based virtual reality trainers. Furthermore, performance metrics are somewhat limited to time to complete a task and penalties for committing predefined errors. Complex motion metrics such as path length and velocity of the instrument tips are not typically measured, as they can be in computer-based simulators. The added value to these computer-derived metrics in terms of training and assessment has yet to be proven. The American College of Surgeons and the Society of American Gastrointestinal and Endoscopic Surgeons sponsor a simulation-based laparoscopic skills training and assessment program known as the Fundamentals of Laparoscopic Surgery (FLS). The manual skills curriculum for FLS takes place in a video trainer, partly because of the cost-effectiveness, reliability, and reproducibility of the tasks in this environment. The FLS manual skills curriculum has been extensively validated. In fact, it is now a “high-stakes” examination that surgeons need to pass to be certified by the American Board of Surgery.⁴⁵

VIRTUAL REALITY SIMULATORS

Driven by extensive use of virtual reality (VR) simulators by the aviation industry, such simulators were introduced to teaching facilities toward the end of the 20th century. Basic VR simulators offer a limited variety of component skills, such as clipping, cutting, suturing, and use of diathermy. More advanced VR simulators rose to the challenge and enabled trainees to practice full laparoscopic procedures, such as cholecystectomy, ventral hernia repair, and even gastric bypass. Several studies, including a recent meta-analysis,⁴⁶ have shown the added value of VR simulators compared with standard laparoscopic training and its supplemental role to box training. An important drawback is that in contrast to flight simulators, where the variability is limited, anatomic variations are common; thus, skills acquired on a simulator may not be applicable in patients. Moreover, VR simulators lack the important tactile sensation of both instrument handling and tissue grasping and resistance. In addition to the relatively expensive pricing of VR simulators, proper maintenance is both time and resource consuming.

AUGMENTED REALITY

After VR simulators were introduced, the obvious next step was to develop a simulator that would feature tactile

sensation. This was accomplished by augmented reality simulators. These simulators provide both realistic haptic feedback and objective assessment after the performance.⁴⁷ With these two important characteristics, augmented reality simulators are considered ultimate training instruments. As with VR simulators, the main disadvantage is pricing and relatively high maintenance.⁴⁸ Both augmented reality and VR simulators have a limited number of programs available for full procedure practice, but constant development of new features promises an exciting future. Although tactile sensation is a major advance in laparoscopy simulators, it cannot replicate the actual haptic feedback for the trainee using the box trainer.

TRAINING PROGRAMS

It is now mandatory that all general surgical training programs in the United States have a skills laboratory. It is possible to create a functional skills laboratory with a relatively small investment. Old laparoscopic equipment can often be attained for a significant discount or donated by the hospital or the equipment manufacturer when new equipment is purchased or upgraded. Skills laboratories offer unique advantages that complement the traditional teaching in the operating room. Procedures and specific parts of procedures may be repeated as needed until a satisfactory level is reached. The laboratory can be accessed at all times and does not depend on the operating room schedule. Running a successful surgical skills laboratory does require a significant investment in terms of time (on behalf of the trainees and the trainers). A specific curriculum is vital, and it should be mandatory that trainees participate in the curriculum with protected time built into their schedule. Extensive practice is well known to improve surgical laparoscopy skills and technique, and it is therefore important to incorporate a skills laboratory schedule in to the curriculum.

Conversion to Open Surgery: When and Why

Laparoscopic surgery may be better than open surgery in several aspects, but conversion to open surgery is often necessary and should not be regarded as a complication. Every surgeon who attempts to complete a laparoscopic procedure must be prepared to convert to open traditional surgery under certain circumstances. An open surgery tray and instruments should always be available inside the operating theater during every laparoscopic procedure. The final decision to convert to open surgery is always made by the senior surgeon. There is no substitution for good judgment and clinical experience, but several guidelines may be considered and are outlined below.

INABILITY TO OBTAIN PNEUMOPERITONEUM

In some patients, it is very difficult to establish pneumoperitoneum. Patients with multiple previous abdominal procedures constitute the majority of this group.⁴⁹ Similarly, patients with distended abdomens attributable to severe ascites, distended bowel, or organomegaly may pose an obstacle in obtaining satisfactory pneumoperitoneum. Female patients with advanced pregnancy are another group that may benefit from open surgery.^{50,51}

LACK OF PROGRESS

Patients are exposed to additional risks as a result of prolonged anesthesia and surgery, such as rhabdomyolysis, hypothermia, disseminated intravascular coagulation, and deep vein thrombosis. Conversion attributable to a lack of progress is defined as being undertaken to avoid complication. The reasons for such conversion include lack of progression caused by unclear anatomy, obesity, and adhesions, among others. Such conversions were demonstrated to be associated with a better outcome than conversions reactive to intraoperative complications.⁵² It is often difficult for the surgeon to correctly evaluate lack of progress and decide on conversion to open surgery. Nevertheless, a carefully timed decision is important and may reduce complications.

PATIENT INSTABILITY

Hemodynamic instability is considered one of the only remaining formal contraindications for laparoscopic surgery. In cases where the patient becomes hemodynamically unstable during a laparoscopic procedure, the laparoscopic insufflation must be stopped and the need for conversion to open surgery must be evaluated.

UNCONTROLLED BLEEDING

Visualization is critical in every surgical procedure but to a greater extent during laparoscopic surgery because of the limited access. The ability to control bleeding (e.g., via packing) is limited in laparoscopic procedures; moreover, small amounts of blood absorb the light, thereby decreasing visibility. Bleeding in laparoscopic cholecystectomy has been shown to increase rates of common bile duct injuries.⁵³ Bleeding that is difficult to control should prompt the surgeon to evaluate the need to convert to open surgery.

POSSIBLE COMPROMISE OF ONCOLOGIC FUNDAMENTALS

Although laparoscopic surgery has been proven to be equal to open surgery for many malignancies, conversion to open surgery should be considered in certain oncologic circumstances. Large adrenal adenocarcinomas and high-stage gallbladder malignancies are better treated with open surgery. Similarly, large and locally invasive upper foregut and hepatobiliary malignancies, large retroperitoneal sarcomas, and others may also be better managed by open resection and, in some cases, managed only that way. Laparoscopic surgeons should never compromise basic oncologic fundamentals such as free margins or adequate lymphadenectomy.

With regard to the number of nodes retrieved, laparoscopy is not inferior to open surgery for esophageal, gastric, and colorectal cancer, while still offering the usual benefits of laparoscopic surgery. Long-term oncologic outcomes are reportedly similar for colorectal cancers but are still under scrutiny for the others.^{7–10,16}

SURGEON EXPERIENCE

Every laparoscopic procedure has its learning curve, and every surgeon must rationally understand his or her location on that learning curve. Although there is no consensus on the number of cases that constitute the learning curve for each procedure, it is agreed that this number increases with the procedure's complexity. For example, some studies document that a plateau in the complication rate is reached after 30 laparoscopic cholecystectomies, but the estimated number of laparoscopic gastric bypasses required to reach the same plateau is 75 to 100. Minimally invasive or laparoscopic clinical fellowships require completion of at least 150 advanced laparoscopic procedures and thus place their graduates at a higher level of performance.^{54,55}

INSTRUMENTAL OR EQUIPMENT FAILURE

Laparoscopic surgery involves numerous instruments and ancillary equipment, and its failure, although rare, may lead to the need for conversion to an open procedure. In non-experienced facilities, equipment failures are more prone to happen.⁵⁶ Preoperative confirmation that all equipment is working satisfactorily does not guarantee avoiding intraoperative failures.

Single Port or Single Incision Laparoscopic Surgery

A recent investigational technique under scrutiny is single port or single incision laparoscopic surgery. It uses a larger trocar, usually inserted through a periumbilical incision that can accommodate the camera, insufflator, and special angled laparoscopic instruments that enable traction as well as dissection through a single port. The skin incision is at least 20 mm long, and the fascial incision is 25 mm. It has been applied in limited circumstances, such as cholecystectomies and adjustable gastric banding, among others. It has not yet gained widespread acceptance because of the challenge of operating without the usual triangulation with standard trocars and because its benefit seems to only be cosmetic.

Conclusion

Laparoscopic surgery is an integral part of general surgery. An understanding of the different technical aspects of laparoscopic surgery is fundamental to performing basic and advanced procedures correctly, as well as to avoid some predictable difficulties and complications. Specific training to acquire laparoscopic skills is mandatory and essential. General surgery trainees and surgeons who wish to use laparoscopic techniques in their practices should participate in structured training programs using training models and operating room proctoring.

Financial Disclosures: Dr. Haggi Mazeh has received an educational fellowship grant from Ethicon Endosurgery.

24 ROBOTIC SURGERY

Satoru Osaki, MD, PhD, Brian Nam, MD, James D. Maloney, MD, FACC, and Tracey L. Weigel, MD, FACS, FACC

The term “robot” was first used by the Czech playwright Karel Capek in 1920 in his play *Rossum’s Universal Robots*. The word is derived from the Czech noun “robota,” which means “drudgery” or “forced labor.” According to the *Oxford Dictionary*, the definition of “robot” is a machine capable of carrying out a complex series of actions automatically, especially one programmable by a computer.¹ Robots have revolutionized industrial production, from automobiles to pharmaceutical manufacturing, and offer an exciting, novel approach to surgical diseases. Robots employed in surgical use initially raised some concern related to malfunction and independent action. However, the surgeon’s decision-making capability is still crucial for each surgical procedure because of the anatomic or physiologic variables of each clinical situation. Currently, surgical robots consist of instruments that are remotely manipulated by a surgeon using an electromechanical interface and represent extensions of the surgeon’s mind and hands. In the future, surgical robots may be directed from remote locations and may even have computer-controlled or autonomous function.

The development of robotic surgery is the direct result of a number of contributing efforts, such as telepresence surgery, military medicine, and video-assisted endoscopic surgery.² The concept of telepresence surgery was that the surgeon did not need to be at the patient’s side to conduct the operation. Surgical robots manipulated by the surgeon from a remote site performed the actual procedure. This telepresence surgical system was created as a collaboration between researchers at NASA and engineers at the Stanford Research Institute in the late 1980s.³ This first model was a one-arm system that allowed the surgeon to manipulate a remote object and perform open surgical stabilization of battlefield trauma patients. Basic feasibility was demonstrated but has not been used in an actual battlefield scenario.⁴ However, the concepts of this initial system, such as three-dimensional (3-D) visualization, heightened dexterity, and fine-instrument manipulation, have been incorporated into the current surgical robotic systems.

The development of videosurgery or video-assisted endoscopic surgery is closely related to that of robotic surgery. Videosurgery came about as the direct result of the development of the cystoscope. In the earliest days of medicine, physicians have sought ways of looking into the living human body. In 1806, Philipp Bozzini invented an instrument that was the ancestor of the modern endoscope, the *Lichtleiter*, which was a sharkskin-covered instrument housing a candle within a metal chimney. In 1853, Antoine Desormeaux in Paris, considered by some to be the “father of endoscopy,” devised brighter illumination via the use of alcohol, turpentine, and a planoconvective focusing lens.⁵ In

1878, true endoscopy was born. Maximilian Carl-Friedrich Nitze, a German urologist, incorporated the revolutionary concept of distal illumination using a heated platinum filament and devised the forerunner of the modern cystoscope.⁶ In 1966, Kurt Semm performed the first laparoscopic gynecologic procedure.⁷ During the 1970s and 1980s, laparoscopy was used for the diagnosis and staging of pathologic processes in the abdomen, and the first laparoscopic cholecystectomy was performed in 1985.⁸ Following the advances of laparoscopic minimally invasive surgery in the abdomen, video-assisted thoracoscopic surgery (VATS) was born in the 1990s.

Video-assisted endoscopic surgical techniques play a significant role in the armamentarium of virtually all surgical subspecialties. However, these techniques are often not sufficient and have the following limitations: (1) current camera systems are two-dimensional images and usually driven by an assistant and not by the surgeon and (2) the instruments for video-assisted minimally invasive surgery are operated on a fixed fulcrum and there is limited range of motion, diminished tactile feel, and exaggeration of a surgeon’s natural tremor.

To address these limitations of conventional videoendoscopic techniques, computer-enhanced instrumentation was developed in the 1990s. The first computer-enhanced surgical instrument was RoboDoc (Integrated Surgical Systems, Sacramento, CA) in 1992, which enabled precise drilling of the shaft of the femur by orthopedic surgeons.⁹ The AESOP (Automated Endoscopic System for Optimal Positioning; Computer Motion Inc, Santa Barbara, CA) [see Figure 1] was introduced in 1993.¹⁰ AESOP’s primary purpose was to hold and maneuver an endoscope and provide a stable field of vision directed by the surgeon’s voice commands. The HERMES system (Computer Motion Inc, Santa Barbara, CA) [see Figure 2] was designed to allow the surgeon to control nearly every aspect of the minimally invasive operative theater, including the laparoscopic camera, lights, telephone, and table function.¹¹ AESOP is still available for purchase, with support for preexisting HERMES systems.

In the late 1990s, two robotic surgical systems were introduced to provide a surgeon with the ability to perform laparoscopic surgery with full control of not only the environment and the camera but the instruments as well. The da Vinci robotic surgical system (Intuitive Surgical, Sunnyvale, CA) [see Figure 3] was introduced in 1997. The first clinical robotic procedure performed with the da Vinci system was a cholecystectomy performed by Cadiere and colleagues in 1997.¹² The first robot-assisted cardiac procedure was performed in 1998,¹³ and the first totally endoscopic coronary artery bypass grafting was performed in 1998.¹⁴ In 2000, the Food and Drug Administration (FDA) approved the da Vinci system for general surgery. The other robotic surgical system, the ZEUS Surgical System (Computer Motion Inc)

Financial disclosure information is located at the end of this chapter before the references.

[see Figure 4], was introduced in 1998. The ZEUS is credited with many clinical firsts in the field of cardiac surgery and was also used for the first clinical robotic nephrectomy. However, the ZEUS system is no longer sold worldwide.

The two robotic surgical systems share a similar concept. Both systems have a surgeon console connected by an

Figure 3 The da Vinci robotic surgical system. Courtesy of Intuitive Surgical (Sunnyvale, CA), with permission.

electronic interface to robotic arms that are driven by cables and used to manipulate the videoendoscope and surgical instruments. The ZEUS Surgical System has an open workstation that gives the surgeon direct external view of the operating room [see Figure 4]. The ZEUS arms consist of three separate working arms that are independently mounted to the operating table [see Figure 5]. A potential advantage of the ZEUS system over the da Vinci system is that the arms can move with changes in table position. The instrument arms are controlled by the surgeon sitting at a console via form-fitted handles. The operation is visualized on a flat monitor but with a computer-simulated 3-D visualization system. The instruments used with this system have 6 degrees of freedom (MicroWrist). The fundamental difference

Figure 5 The ZEUS robotic arms. Courtesy of Intuitive Surgical (Sunnyvale, CA), with permission.

between the da Vinci and ZEUS systems is that the da Vinci system has all of its robotic arms on a self-contained robotic cart, and the console has all of its features integrated into one ergonomic unit. The da Vinci system has a console with two independent LCD monitors in front of the surgeon's eyes. With this system, the surgeon has true 3-D vision generated by a binocular camera and is immersed into the surgical field. Also, the da Vinci has 7 degrees of freedom with its instruments (EndoWrist) and hand positioning at the console. These features combine to give a more realistic impression that the robotic instruments inside the patient are actually extensions of the surgeon's hands. Recently, the da Vinci Si [see Figure 6] was introduced and has a fourth instrument arm that serves as a substitute for a second human assistant. The da Vinci Si has a dual console capability,

Figure 6 The da Vinci Si. Courtesy of Intuitive Surgical (Sunnyvale, CA), with permission.

which enables two surgeons to control the instruments and perform the procedure.

With the cumulative effect of the robotic system, surgeons may be able to perform complex procedures beyond the capabilities of conventional videoendoscopic techniques. As of this writing, over 800 hospitals in the United States are currently using the da Vinci surgical robotic system. The FDA has approved the da Vinci Surgical System for use in urologic surgical procedures (radical prostatectomy, pyeloplasty, cystectomy, nephrectomy, and urethral reimplantation), general laparoscopic surgical procedures (cholecystectomy, Nissen fundoplication, Heller myotomy, gastric bypass, adrenalectomy, splenectomy, and bowel resection), gynecologic laparoscopic surgical procedures (hysterectomy, myomectomy, and sacrocolpopexy), transoral otolaryngology surgical procedures (oropharyngeal, laryngeal, and hypopharyngeal resections), thoracic surgical procedures, and thoracoscopically assisted cardiectomy procedures (internal mammary artery [IMA] mobilization, cardiac tissue ablation, mitral valve repair, endoscopic atrial septal defect [ASD] closure, and coronary artery anastomosis for cardiac revascularization). In the following sections, particular surgical subspecialty uses of robotic surgery, specifically cardiac surgery, general surgery, and thoracic surgery, are described in detail.

Cardiac Surgery

During the last century, cardiac surgery has undergone several paradigm shifts.¹⁵ The first successful cardiac operation for heart stab wounds was performed in 1896 by Rehn,¹⁶ followed by the first successful cardiac valve operation in 1912 by Tuffier.¹⁷ The innovation of cardiopulmonary bypass (CPB) allowed for the repair of intracardiac lesions. In 1953, Gibbon closed a large secundum ASD using CPB.¹⁸ Since then, cardiac surgery has stepped out of its infancy and expanded to more complex diseases.

In the 1990s, the successes of laparoscopic operations in general surgery sparked an interest in minimally invasive approaches for cardiac surgery. In the mid-1990s, minimally invasive direct coronary artery bypass (MIDCAB) through a small thoracotomy and without CPB appeared in the literature.¹⁹ Navia and Cosgrove and Cohn and colleagues performed the first minimally invasive valve operations via a right parasternal and transsternal incision.^{20,21} In 1996, Carpentier and colleagues performed the first video-assisted mitral valve repair (MVR) through a mini-thoracotomy.²² Soon thereafter, they also performed the first completely robotic MVR using the da Vinci robotic surgical system²³ and the first case of a robot-assisted totally endoscopic coronary artery bypass grafting (TECABG).¹⁴

Over the past decade, a number of cardiac surgical procedures have been adapted to be performed endoscopically with robotic assistance. Currently, robotic cardiac surgical techniques are being applied to IMA harvest, coronary artery bypass grafting (CABG), valvular heart diseases, closure of ASDs, treatment of atrial fibrillation (AF), and therapies such as resynchronization for congestive heart failure.

ROBOTIC IMA HARVEST

The use of the left internal mammary artery (LIMA) for CABG has been shown to impart a clear survival advantage

for patients with single- or multivessel coronary artery disease.²⁴ Traditionally, the LIMA has been harvested via a full sternotomy; MIDCAB was proposed as an alternative to conventional CABG. In this procedure, the LIMA is partially harvested under direct vision via a partial sternotomy. However, inadequate mobilization of the LIMA caused avulsion and coronary steal syndrome,²⁵ which led to reluctance toward adoption of this technique. Thoracoscopic LIMA harvest was explored as an alternative.²⁶ However, most cardiac surgeons found this technique to be cumbersome, time consuming, and limited by the mobility of conventional thoracoscopic instruments. To solve these limitations, robotic surgical systems have been used with great success for LIMA harvest.

Single-lung ventilation using double-lumen endotracheal intubation is required.² The patient is positioned in the supine position on the operating table with a roll under the left shoulder to elevate the shoulder 30°. Three ports are then placed. The camera port is introduced in the left fifth intercostal space, the right robotic arm is placed in the left third space, and the left arm is placed in the sixth to seventh space, in the same line as the camera port. After accessing the left pleural space, a 30° endoscope is used and CO₂ insufflation is performed. The LIMA is identified and dissected from the chest wall from the first intercostal branch superiorly to the diaphragmatic border inferiorly.

There is an initial learning curve with the technique of robotic LIMA harvest. Kappert and colleagues reported 61 patients who underwent robotic LIMA harvest, and the median time for LIMA takedown was 50 ± 16.9 minutes.²⁷ Mohr and colleagues reported a median time of LIMA harvest of 48 ± 26.3 minutes and was under 40 minutes for the last 20 patients.²⁸ These studies show that the robotic surgical system provides excellent exposure for a safe LIMA harvest with acceptable harvesting times. The technique of robotic LIMA harvest is the initial step for robot-assisted single- or multivessel CABG.

MINIMALLY INVASIVE ROBOTIC CABG

CABG has been the mainstay for cardiac surgery for the last three decades. With the thrust toward minimally invasive surgery, cardiac surgeons have investigated operations designed to minimize the invasiveness of CABG. Coronary revascularization has evolved from on-pump CABG to off-pump procedures to MIDCAB/TECABG. Since the robotic surgical system has become available, single- or multivessel CABG with robotic IMA harvest can be performed via a small anterior thoracotomy. In 1998, Loulmet and colleagues performed the first case of a robot-assisted minimally invasive single-vessel TECABG.¹⁴ In 2000, Kappert and colleagues reported a robot-assisted two-vessel TECABG using bilateral IMAs.²⁷ Robot-assisted TECABG is currently limited to single-vessel (left anterior descending artery [LAD]) disease or occasionally two-vessel disease.

The operating room setup, anesthesia, patient positioning, and port placement are similar to those for robotic IMA harvest.² After completion of the IMA harvest, the camera port incision is lengthened and the arterial anastomosis is performed under direct visualization. The pericardium is opened along the suspected course of the LAD, the beating

heart is stabilized with devices (i.e., the Endostabilizer, Estech Corp, Danville, CA) or the endoscopic cardiac positioner (Starfish NS Medtronic Inc, Minneapolis, MN), and the IMA is anastomosed to the LAD.

In 2001, the FDA sanctioned a multicenter study of the safety and efficacy of the da Vinci system for robot assisted TECABG.²⁹ Ninety-eight patients requiring single-vessel LAD revascularization were enrolled at 12 centers between 2002 and 2004. Thirteen patients were excluded intraoperatively. In 85 patients who underwent TECABG, the CPB time was 117 ± 44 minutes and the cross-clamp time was 71 ± 26 minutes. There were no deaths or strokes, but there was one early reintervention and one myocardial infarction. Six patients were found to have a significant anastomotic stenosis at the 3-month follow-up angiography. This trial showed the safety of robot-assisted TECABG. Currently, this procedure is performed in a highly selected group with limited coronary disease. With continued technological advances, robotic coronary bypass surgery will become applicable to a wider patient population.

ROBOTIC MITRAL VALVE SURGERY

Traditionally, mitral valve surgery has been performed via a median sternotomy. Since the mid-1990s, minimally invasive mitral valve surgery via a small thoracotomy has become popular. Large series by Navia and Cosgrove and Cohn and colleagues showed that surgical mortality and morbidity were comparable to those of conventional mitral surgery.^{20,21} With experience, a shift from direct vision, to video-assisted, to robot-assisted techniques has occurred. In 1996, Carpentier and colleagues performed the first video-assisted MVR via a right mini-thoracotomy,²² and Mohr and colleagues reported the first case of “solo mitral surgery” using the AESOP system in 1997.²⁸ In 1998, Carpentier and colleagues performed the first truly robotic MVR using an early prototype of the da Vinci system.²³ In the United States, the first FDA safety and efficacy multicenter trial was performed in 2000³⁰ and the da Vinci system for mitral surgery was FDA approved in November 2002.

Currently, the following robot-assisted MVR procedures have been performed: robotic mitral valve triangular or quadrangular leaflet resection, posterior leaflet sliding repair, chordal transfer, expanded polytetrafluoroethylene (ePTFE) artificial chord replacement, resection annuloplasty, and annuloplasty band insertion.² Patients are prepared with the right side elevated by 30°. Cannulation for CPB is performed through the right femoral artery and vein and the right internal jugular vein. The camera port is placed in a 3 to 4 cm mini-thoracotomy incision on the right fourth ICS, and two robotic arms are inserted through the third and fifth ICSs. After accessing the pericardial space, the interatrial groove is dissected, the ascending aorta is clamped with the transthoracic aortic cross-clamp (Cardioventions Inc., Somerville, NJ), and the procedure is performed.

Chitwood and colleagues reported the largest single-center robotic MVR experience.³¹ In their series, 300 patients underwent robotic MVRs, including triangular leaflet resections, sliding repairs, chordal transfers or replacements, edge-to-edge approximations, and ring annuloplasties. The 30-day mortality was 0.7%, and late mortality was 2.0%. Five-year survival was 96.6% ± 1.5%, with 93.8% ± 1.6% freedom from reoperation. These initial results are encouraging,

and with continued advances in technique, this procedure should become more prevalent.

ROBOTIC MODIFIED MAZE OPERATION

The Maze operation was introduced by Dr. James Cox in 1987.³² The Cox-Maze procedure was designed to interrupt any and all macroreentrant circuits that might potentially develop in the atria, thereby precluding the ability of the atrium to flutter or fibrillate. A reiteration of this original procedure, the Cox-Maze III, has become the gold standard in the surgical treatment of AF. This procedure requires a full sternotomy; thus, patients with AF alone have been reluctant to undergo this procedure. Less invasive, catheter-based techniques have been effective for intermittent AF but have a significant failure rate for continuous AF.

The robotic Maze operation first began as a concomitant procedure to the robotic MVR but has since been performed on its own. Garrido and colleagues described 62 patients who underwent combined AF and mitral valve surgery, half with the da Vinci and half with the AESOP.³³ A variety of energy sources were used, including radiofrequency, microwave, and cryoablation. Operative mortality was 4.8%, with 65% of patients in normal sinus rhythm at the time of discharge. Twenty-seven percent of patients remained in AF, and 8% required pacemaker implantation at the time of discharge. The robotic Maze operation has not become a common procedure yet; however, with improved devices and continued success from pioneering centers, it may become a widely available clinical reality in the near future.

ROBOTIC CARDIAC RESYNCHRONIZATION THERAPY (EPICARDIAL PACEMAKER LEAD PLACEMENT)

Cardiac resynchronization therapy (CRT) is an adjuvant treatment for the patients with congestive heart failure and intraventricular conduction delay. Prospective, randomized trials have demonstrated improvements in ventricular function, exercise capacity, and quality of life among patients undergoing ventricular resynchronization therapy via biventricular pacing.^{34,35} Usually, the left ventricular (LV) lead implant is performed percutaneously through coronary sinus cannulation and advancing the lead into a major cardiac vein. However, technical limitations attributable to individual variations in coronary sinus and coronary venous anatomy result in a 10 to 15% failure,³⁶ and lead dislodgment contributes to an additional 5 to 10% late failure rate.³⁷ When percutaneous lead placement is unsuccessful, rescue therapy for these patients has typically involved LV epicardial lead placement via an anterior thoracotomy. This approach is limited by both its morbidity and access to the posterolateral surface of the left ventricle. Therefore, minimally invasive techniques including VATS or robotic-assist LV epicardial lead placement were developed. Recently, Joshi and colleagues reported a follow-up result for 42 patients with robotic LV epicardial lead placement.³⁸ Eighty-four epicardial lead placements were performed, and the operative time was 51 ± 32 minutes. LV injury and pleural adhesions necessitated conversion to mini-thoracotomy in two patients. This experience showed that robotic LV epicardial lead placement was safe and effective and should be considered when percutaneous approaches have been unsuccessful.

ROBOTIC CLOSURE OF ATRIAL SEPTAL DEFECT

ASD is one of the most common adult congenital heart defects. There are several different types of ASD: the secundum ASD in the region of the fossa ovalis (75% of cases), the primum ASD (15 to 20%) positioned inferiorly near the crux of the heart, the sinus venosus ASD (5 to 10%) located superiorly near the superior vena caval entry or inferiorly near the inferior vena caval entry, and the uncommon coronary sinus septal defect (less than 1%), which causes shunting through the ostium of the coronary sinus.³⁹ Traditionally, surgical treatment of secundum ASDs required a sternotomy. Since the development of percutaneous transcatheter closure techniques, the majority of secundum ASDs can be closed with a percutaneous catheter technique.⁴⁰⁻⁴² When this is not feasible, surgical closure is recommended.⁴³ Argenziano and colleagues reported the first US experience of totally endoscopic ASD repair with the da Vinci system in 2003.⁴⁴ Seventeen patients underwent repair of a secundum ASD ($n = 12$) or patent foramen ovale ($n = 5$) via a totally endoscopic approach. The aortic cross-clamping time was 32 minutes, and the CPB time was 122 minutes. In 16 patients, transesophageal echocardiography after 30 days confirmed successful repair. The median hospital length of stay was 4 days. A robotic approach is an option for patients with secundum ASD that is not appropriate for percutaneous repair who wish to avoid sternotomy or thoracotomy.

General Surgery

Since the innovation of the endoscope and the evolution of laparoscopic procedures in the 1970s and 1980s, general surgical procedures have dramatically switched from open to minimally invasive approaches. For example, the first laparoscopic cholecystectomy was performed in 1985⁸ and had become the standard procedure by the mid-1990s. The initial application of laparoscopic surgery was attractive because of the potential benefits, such as minimal incision, decreased postoperative morbidity, and a reduction in the total length of hospital stay.⁴⁵

In the development of robotics for general surgery, the first active robotic device for laparoscopic surgery was the voice-controlled endoscopic camera positioning system (AESOP). AESOP replaced the cameraperson, facilitated the performance of solo-surgeon laparoscopic operations, and provided a stable camera platform, avoiding motion sickness in the operative team.⁴⁶ Subsequently, the introduction of the da Vinci robotic system afforded the ability to perform laparoscopic surgery with full control of up to three surgical instruments and the camera. The first clinical robotic cholecystectomy was performed by Cadiere and colleagues in 1997.¹² In July 2000, the FDA approved the da Vinci system for general laparoscopic surgery such as cholecystectomy, Nissen fundoplication, Heller myotomy, gastric bypass, adrenalectomy, splenectomy, and bowel resection.

Potential advantages of the da Vinci system include tremor reduction, 3-D visualization, and wrist action at the surgical site compared with traditional laparoscopic instruments. However, over 10 years have passed since the first clinical application for robotic cholecystectomy, yet robotics has not been widely adopted into general minimally invasive surgery. One possible reason for this is that the da Vinci

system was primarily designed for cardiac surgery and, thus, is not configured for abdominal surgery.⁴⁷ Also, this system still has limited instrumentation and bulky arms and lacks tactile feedback. Lack of tactile feedback calls for expertise in interpreting visual cues to maneuver instruments in three dimensions and cannot accurately reflect how tightly tissues are grasped with instruments. The robot currently has no instrumentation for surgical stapling or a sealing and cutting instrument, which are both commonly used in bowel surgery, although both are “on the imminent horizon.” Many general laparoscopic procedures require moving throughout multiple quadrants in the abdomen, which is difficult with the robot. Compared with traditional laparoscopic systems, the da Vinci system is very bulky, and repositioning of the da Vinci arms requires a great deal of effort. In addition, the robot systems cost more than \$1 million, and the clinical results for general surgery procedures are, at best, comparable, not superior, to procedures with much cheaper laparoscopic instrumentation.

Currently, the da Vinci Surgical System has been used primarily in general surgery to perform: Heller myotomies, antireflux surgery, bariatric surgery, cholecystectomy, splenectomy, gastrectomy, and colorectal surgery.^{2,48} This section describes these particular robotic procedures briefly and the potential advantages and disadvantages of robotic approaches compared with conventional laparoscopic approaches.

ROBOTIC HELLER ESOPHAGEAL MYOTOMY

Achalasia is the most common primary motility disorder of the esophagus. The distinctive findings are the absence or primary peristalsis of the esophagus body and the increased or normal pressure of the lower esophageal sphincter (LES) that fails to relax in response to swallowing. The surgical treatment is to relieve the outflow obstruction at the level of the LES. Today, a Heller myotomy is considered the standard surgical procedure, relieving symptoms in approximately 85 to 90% of patients.⁴⁹ The laparoscopic Heller myotomy became the preferred approach in the mid-1990s.⁵⁰ In 2000, Melvin and colleagues reported the first robotic Heller myotomy using the da Vinci Surgical System.⁵¹ In terms of potential advantages of robotics in Heller myotomy, the working area, that is, the lower posterior mediastinum or upper abdomen, is small and often difficult, and the freedom of movement of the articulated robotic instruments enables the surgeon to operate with dexterity in this narrow field. Furthermore, the 3-D vision allows each individual muscular fiber to be visualized and divided, facilitating the accuracy of the myotomy. A superior view of the submucosal plane, as afforded by the da Vinci system, could potentially reduce the risk of mucosal perforation.²

When compared with standard laparoscopic Heller myotomy series, the current studies showed no esophageal perforations in a robotic procedure (0 of 102) and 11% (17 of 150) of esophageal perforations with 8 times fewer patients with robotic Heller myotomy suffering from this problem.⁴⁸ Hufmann and colleagues reported that the postoperative quality of life of the patients with robotic Heller myotomy was improved with respect to the role played and the general perception of health (two of nine categories).⁵² However, meta-analysis of these studies revealed no differences

in blood loss, surgery time, and the length of hospital stay.⁴⁸ In summary, the robotic Heller myotomy appears to be associated with a much lower risk of perforation and a better quality of life in experienced institutions.

ROBOTIC NISSEN FUNDOPLICATION

Considerable experience has now been acquired with robotic fundoplication for reflux disease. The patient is placed in the lithotomy position, and five trocars are placed. A 12 mm camera is placed supraumbilically, and two 7 mm trocars are placed in the midclavicular lines at the costal margin on either side for each robotic arm. Then a 10 mm trocar is placed laterally at the right subcostal margin, which functions as a liver retractor, and a 12 mm trocar is placed on the left side of the patient as an accessory port. The procedure itself follows much in the same way that it is performed laparoscopically.⁵³ Studies thus far have shown this approach to be safe, with similar results and outcomes when compared with laparoscopic fundoplication. However, longer operative times and higher total costs associated with the robotic device itself have limited the widespread adoptance of this procedure.⁵⁴

ROBOTIC BARIATRIC SURGERY (ADJUSTABLE GASTRIC BANDING AND GASTRIC BYPASS)

Laparoscopic Roux-en-Y gastric bypass operations are among the most difficult operations performed by even experienced laparoscopic surgeons. One must be able to suture, perform intracorporeal knots, and manipulate bowel throughout the entire abdomen within the limits of laparoscopic equipment.⁵⁵ Recently, a robotics approach has been developed that may reduce some of these technical difficulties. Six ports are used for the robotic procedure. A camera port is placed in the umbilicus, and five ports are strategically placed in the periphery of the upper abdomen. The results of a robotic gastric bypass when compared with a laparoscopic gastric bypass are similar in regard to operative time, outcomes, and hospital stay.⁴⁸ However, although there may be no differences in these aspects, a robotic approach may be easier to learn. It took less time to complete the procedure using a robot-assisted versus a standard laparoscopic approach for surgeons new to both procedures.⁵⁶ With further refinement of the robotic approach, these advantages may become more evident.

ROBOTIC CHOLECYSTECTOMY

Since the advent of laparoscopic cholecystectomy in the late 1980s, this procedure has become one of the most common procedures performed by general surgeons today. The benefits of laparoscopic cholecystectomy versus open cholecystectomy are well documented and include a shorter hospital stay and a quicker convalescence.⁵⁷ Robotic cholecystectomy was one of the first applications of the robotic device in general surgery. The setup and incisions used in both operations are similar. The patient is placed in the supine position, and four ports are placed in the upper abdomen. A study from 2008 comparing 50 robotic cholecystectomies with 50 laparoscopic cholecystectomies showed similar operating times, complication rates, and hospital stay between the two groups.⁵⁸ However, the total cost of a robotic cholecystectomy was significantly higher, which was

directly related to the cost of the robotic device. Thus far, robotic cholecystectomy has been shown to be safe but has not yet supplanted laparoscopic cholecystectomy.

ROBOTIC SPLENECTOMY

Robotic splenectomy has been performed with outcomes similar to those of the laparoscopic approach, although surgeons note the benefit of increased magnification and precision of the da Vinci instruments.⁵⁹ Only one study to date has compared the two. Bodner and colleagues reported their experience of 12 minimally invasive splenectomies (six robotic splenectomies via the da Vinci system and six laparoscopic splenectomies).⁶⁰ In this series, the robotic procedure was associated with an average increase of \$2,800 in total cost. The mean operative time with the robotic procedure was also 30 minutes longer, although this increase was not significant. The length of hospital stay was similar with both surgical methods (6 to 7 days), as was blood loss. No surgical conversions were necessary with either technique, nor was either associated with any major complications. It is hard to conduct any significant conclusions from a single study, although the information it provides suggests that the robotic approach is more expensive and tends to be a longer procedure than its laparoscopic counterpart.

ROBOTIC GASTRECTOMY

A laparoscopic approach for early-stage gastric cancer was introduced in the early 1990s. Subsequently, with the development of the da Vinci Surgical System, Hashizume and colleagues reported the first experience of robotic distal gastrectomy in 2002.⁶¹ Published results have been limited thus far. In 2010, Kim and colleagues reported their experience of 39 gastrectomies, including 16 robotic, 11 laparoscopic, and 12 open approaches, and compared these three groups to determine the clinical benefits of robotic gastrectomy.⁶² The estimated blood loss was significantly less in the robotic gastrectomy group than in the open group, and the postoperative hospital stay in the robotic group was significantly shorter than in the open and laparoscopic gastrectomy. This study demonstrates the feasibility of robotic gastrectomy and shows that there may be some benefit to this approach.

ROBOTIC COLORECTAL RESECTION

Since the first laparoscopic colorectal operation, a right hemicolectomy performed by Jacobs in 1990,⁶³ laparoscopic techniques have been adopted for a wide range of colorectal procedures.⁶⁴ Recently, a prospective, randomized, multi-institutional study demonstrated that the rates of tumor recurrence, overall survival, and disease-free survival after laparoscopy-assisted colectomy were comparable to those of open colectomy in patients with colon cancer.⁶⁵ Perioperative recovery was significantly faster after the laparoscopic procedure, although the operating time was significantly longer. Thus, the laparoscopic approach is becoming the new standard for colorectal disease.

The first robot-assisted colectomy was performed in 2001.⁶⁶ Since that time, several studies comparing robot-assisted and laparoscopic colon surgery have been published.^{67–69} According to these studies, the robotic approach was associated with a longer operating time, higher costs, and similar

outcomes. The robotic approach for total colectomy can be more difficult because of the limited range of motion of the current robotic setup and the need to access the colon in all four abdominal quadrants.⁷⁰ The only potential benefit of the robot for colorectal surgery may be in complex pelvic dissections, where visibility and space for dissection are usually limited.⁵⁹ An early comparative trial of robotic versus laparoscopic total mesorectal excision for rectal cancer showed low complication rates in both arms but a decreased hospital stay in the robotic arm of the study.⁷¹

Thoracic Surgery

Technological advances continue to shape how we approach the chest. The first report of thoracoscopic (VATS) lobectomy was published in 1992.⁷² Subsequently, VATS procedures have been widely adopted, and many studies have demonstrated the multiple advantages of a VATS lobectomy, including decreased postoperative pain, shortened hospital stay, and an increased likelihood that patients proceed to adjuvant therapies.⁷³ Currently, 30% of all lobectomies performed nationwide are via a VATS approach. In the past decade, the advent of robotic surgery has offered a new, perhaps improved, approach to the chest. Robotics has now been used for pulmonary resections and in the mediastinum.

ROBOT-ASSISTED THORACOSCOPIC PULMONARY RESECTION

Experience with robotic pulmonary resections has been limited to date. The advantages of using robotics versus thoracoscopic equipment include 3-D visualization and increased articulation, which are especially beneficial within the confined space of the chest cavity. The positioning of the patient and the incisions used in both operations are similar. The patient is placed in the flexed lateral decubitus position, and four incisions are made. A camera port is placed in the eighth interspace in the midaxillary line, a 3 cm utility incision is placed in either the fourth or fifth interspace, and the left and right arms of the robot are placed in the sixth interspace anteriorly and the seventh interspace posteriorly.⁷⁴ Park and colleagues reported their initial experience with 34 robotic lobectomies.⁷⁵ All types of lobes were removed, and a mediastinal lymph node dissection was performed in all cases. There were no significant intraoperative complications, although four cases were converted to an open thoracotomy. The mean operating time was 218 minutes, and the median length of hospital stay was 4.5 days. As experience accrues, pulmonary resections should become more amenable to robotic resection.

ROBOT-ASSISTED THORACOSCOPIC THYMECTOMY

Mediastinal lesions are perhaps particularly well suited to robotic dissection. The increased visibility and the increased range of motion of the robotic arms allow the surgeon to dissect in the restricted spaces of the mediastinum. There has been much experience already with robotic thymectomy for myasthenia gravis. The patient is placed in the flexed lateral position, and the approach is from the patient's right side given that the heart is encountered on the left. Four ports are used. The right half of the thymus is carefully

dissected away from the pericardium, taking care not to injure the phrenic nerve or innominate vein. Once the right half has been completely freed, attention is then directed toward the left. The robotic arms are maneuvered underneath the sternum, and the left half is carefully dissected paying particular attention to the phrenic nerve on the left. Rea and colleagues reported their experience with 33 robotic thymectomies.⁷⁶ The mean operative time was 120 minutes, there were no open conversions, and there were no significant intraoperative complications. The authors pointed out that dissection of the thymus in the lower neck and in the contralateral side is better facilitated via a robotics approach when compared with a VATS approach. As more experience with robotic thymectomy is gained, this may become the preferred approach to thymic resection.

Financial Disclosures: None Reported

26 CANCER EPIDEMIOLOGY AND PREVENTION

Heather B. Neuman, MD, MS

Cancer remains a significant public health problem in the United States and is now the leading cause of death for men and women younger than 85 years of age.¹ It is estimated that over 1.5 million new cancer cases and 500,000 cancer deaths will occur in the United States in 2010.¹ In addition, over 2 million basal and squamous cell skin carcinomas and 100,000 in situ cancers (primarily breast and melanoma) are expected. This represents a slight decrease in both incidence and mortality over the past decade, with progress being seen across gender and racial and ethnic groups. However, there is still significant room for progress with regard to cancer prevention, screening for early detection, and treatment.

The etiology of cancer development is often multifactorial, although direct links have been made between specific cancer types and environmental exposures, infections, pharmaceutical agents, and hereditary syndromes. The list of known human carcinogens is extensive and is represented in part in Table 1.^{2–7} Select carcinogens from this table are highlighted and expanded on in this chapter.

Although improvements in treatment play an important role in the decrease in cancer-related mortality observed over the past decade, primary prevention and early detection are paramount to progress in minimizing the morbidity and mortality associated with cancer. Primary prevention can occur through a variety of means, including avoidance of exposures (environmental, pharmaceutical, or infectious). Alternatively, direct prevention through chemoprevention or risk-reducing surgery is advocated in some circumstances. Finally, although not a true “prevention” strategy, screening plays an important role in detecting cancers early, especially as noninvasive lesions.

Cancer Epidemiology

PHARMACEUTICALS

Hormone Replacement Therapy

Numerous epidemiologic studies have been conducted evaluating the relationship between hormone replacement therapy and breast cancer risk. Studies evaluating the impact of hormone replacement have been summarized in a large pooled analysis that suggests that a small increase in breast cancer risk exists for ever-users of hormone replacement therapy (relative risk of 1.14), with the risk increasing with duration of use (greater than 5 years).⁸ Importantly, this increased risk appears to disappear within 5 years of cessation of use. However, only 12% of patients in this pooled analysis were taking a combined estrogen and progesterone pill, limiting the ability to draw conclusions on the relationship between

use of combination pills and breast cancer. This is significant as combination pills are the most commonly used form of hormone replacement therapy because of the elevated risk of endometrial cancer observed in women with an intact uterus who take estrogen-only pills.⁹

The best evidence regarding the association between combination pills and breast cancer risk comes from a randomized, controlled trial conducted by the Women’s Health Initiative. The objective of this trial was to evaluate the impact of hormone replacement therapy on chronic disease; postmenopausal women were randomized to combination or estrogen-only replacement based on the presence or absence of a uterus at the time of enrolment.¹⁰ The trial was stopped early in the combination arm because of an increased incidence of breast cancer observed at an interim analysis (hazard ratio 1.24 [95% CI 1.04–1.5]). The risk of breast cancer associated with combination therapy increased with duration of use.¹⁰ These data have been supported in multiple other observational and case-cohort studies and led to the conclusion by the International Agency for Research on Cancer to list both combined and estrogen-only hormone replacement therapy as a human carcinogen.⁹ As a result, the use of hormone therapy in the United States has decreased dramatically since the Women’s Health Initiative was reported.¹¹

INFECTIONS

Infectious agents have been known to be associated with cancer development for some time [see Table 1]. This relationship is significant as avoidance or treatment of these infections is a viable mechanism of cancer prevention and may have a role in cancer treatment. Cancer prevention through vaccination is discussed later in the chapter.

Human Papillomavirus

Human papillomavirus (HPV) is thought to be associated with almost all cervical cancers. Two specific subtypes of virus, HPV-16 and HPV-18, are thought to be responsible for approximately 70% of these cancers.¹² Additionally, the virus has been associated with cervical intraepithelial neoplasia, a preinvasive condition. Knowledge of the importance of this virus in the development of cervical cancer has led to improved screening techniques by combining the Papanicolaou smear with HPV DNA testing.¹³ Furthermore, vaccine development targeting these virus subtypes allows a mechanism of primary prevention.^{14,15}

Hepatitis Virus

Chronic infection with hepatitis viruses is a factor known to be associated with cancer development, specifically

Table 1 Known Human Carcinogens²⁻⁷

	Carcinogen	Cancer Type
Pharmaceuticals	Hormone replacement therapy Estrogen only Combined estrogen-progesterone	Endometrial, ovary Endometrial, breast
	Diethylstilbestrol	Breast (exposure during pregnancy), vagina/cervix (exposure in utero)
	Tamoxifen	Endometrial cancer
	Busulfan, treosulfan	Myelogenous leukemia
	Chlorambucil	Myelogenous leukemia
	Cyclophosphamide	Myelogenous leukemia, bladder
	Azathioprine	Non-Hodgkin lymphoma, skin
	Cyclosporine	Non-Hodgkin lymphoma, skin
	Melphalan	Leukemia
	Phenacetin	Renal pelvis, ureter
	Thiotepa	Leukemia
	Methoxsalen with ultraviolet light	Skin
Infections	Hepatitis B virus	Hepatocellular carcinoma
	Hepatitis C virus	Hepatocellular carcinoma, non-Hodgkin lymphoma
	Human papillomavirus	Cervical, vaginal, vulva, penis, anus, oropharyngeal
	Epstein-Barr virus	Nasopharyngeal carcinoma, Burkitt lymphoma, Hodgkin lymphoma
	Kaposi sarcoma virus	Kaposi sarcoma
	Human T cell lymphotropic virus type I	T cell lymphoma
	<i>Helicobacter pylori</i>	Gastric, mucosa-associated lymphoid tissue (MALT) lymphoma
	<i>Clonorchis sinensis</i>	Cholangiocarcinoma
	<i>Schistosoma haematobium</i>	Urinary bladder
Environmental and naturally occurring compounds	Aflatoxins	Liver
	Arsenic	Lung, skin, urinary bladder
	Beryllium	Lung
	Cadmium	Lung
	Chromium	Lung
	Nickel compounds	Lung, nasal cavity, paranasal sinus
	Asbestos	Lung, mesothelioma, larynx, ovary
	Erionite	Mesothelioma
	Silica dust	Lung
	Radon	Lung
	Wood dust	Nasal sinus
Other	Ionizing radiation	Thyroid, breast
	Tobacco	Lung, mouth, pharynx, larynx, esophagus, stomach, pancreas, bladder, kidney renal pelvis, cervix

hepatocellular carcinoma.¹⁶ Worldwide, hepatitis B is associated with the majority of liver cancers. Fortunately, the widespread availability in the United States of a vaccine against hepatitis B has decreased infection rates. Rates of hepatocellular carcinoma in the United States are actually rising, however, and may parallel the increasing incidence in hepatitis C infection.¹⁷ This is an increasing public health concern given the lack of vaccination or definitive treatment options for this virus.

Helicobacter pylori

Helicobacter pylori is a common infection observed in the United States and has great clinical significance because of the association between infection and ulcer development. However, infection has also been associated with the development of gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphomas.¹⁸ Treatment of the bacteria results in regression of MALT lymphomas and may be preventive for adenocarcinoma development.

OTHER

Ionizing Radiation

Ionizing radiation is well recognized as a human carcinogen.¹⁹ The effects of ionizing radiation have been most widely studied in association with the atomic bombings in Japan. However, significant information also comes from clinical settings where patients were exposed to radiation as a component of therapeutic procedures. Examples include an elevated risk of breast cancer in patients who underwent mantle radiation for Hodgkin lymphoma and increased rates of leukemia in patients who underwent high-dose radiation for cervical cancer. Ionizing radiation can lead to cancer development in almost any tissue, with certain sites, such as thyroid, breast, and bone marrow, being most susceptible. Age at exposure is a determinant of risk, and the greatest risk is in those individuals exposed as children or adolescents.

Significant attention has also been paid to the potential cancer risks associated with diagnostic imaging, especially computed tomographic (CT) scans. Overall, it is estimated that 0.4% of cancers in the United States can be associated with radiation from CT scan use.²⁰ This estimation is based on data from 1991 to 1996. Given the increased application of CT, it is estimated that this figure may now be 1.5 to 2.0%.²⁰ It is important to note, however, that no large-scale epidemiologic studies have been reported that systematically assess this risk. At the current time, the prudent use of CT scans as necessary to facilitate clinical care, with the use of alternative imaging when appropriate, is recommended.

Tobacco

Tobacco use is the leading cause of preventable cancer deaths worldwide and in the United States alone accounts for more than 400,000 premature deaths annually.²¹ Tobacco use is thought to be associated with more than 90% of all lung cancer cases, with multiple prospective epidemiologic studies consistently demonstrating this relationship.²² Smokers have an estimated 10- to 20-fold increase in the risk of lung cancer when compared with nonsmokers, and although some of this risk can be mitigated by smoking cessation, the risk never falls to the level of a lifelong nonsmoker. Risk is related to overall exposure, such as number of cigarettes smoked per day, number of years of active smoking, and depth of inhalation.²² Those individuals exposed to tobacco smoke (passive smoking) also have an elevated risk of lung cancer, estimated to be a 30% increase when compared with other nonsmokers.⁶ As a result, secondhand tobacco smoke has been classified as a known human carcinogen by the Environmental Protection Agency.⁶

Tobacco is also associated with a significantly increased risk of oropharyngeal cancer; this extends to cigarette, pipe, and cigar smoking as well as other smokeless forms of tobacco. This risk can be increased with excessive alcohol consumption. Although alcohol and tobacco both represent independent risk factors for oropharyngeal cancer development, their effects are synergistic and increase risk by 10 to 13 times that of nonusers.²³ Data also support a strong link between tobacco and bladder, esophageal, pancreatic, and gastric cancers.²² The effect size is smaller for these malignancies, ranging from 1.5- to 3-fold increases. Finally, a suggestive but yet unproven

relationship exists for many other malignancies, including breast and colorectal cancer.

Current tobacco use in the United States has remained relatively steady in recent years. Given the significant relationship and cancer burden associated with smoking, programs encouraging smoking cessation are paramount in the prevention of future cancers. Additionally, targeting of at risk-populations to prevent initiation of tobacco use holds great potential in decreasing cancer incidence.

DIET, OBESITY, AND PHYSICAL ACTIVITY

After tobacco use, management of diet and weight are the leading modifiable risk factors associated with cancer development.²⁴ The relationship between these factors and cancer is multifactorial, with other factors, such as genetics and environmental exposures, likely contributing to overall risk.²⁴

Strong support for a link between diet and cancer can be observed through geographic clustering of cancer and changes in cancer incidence observed in immigrant populations. Geographic clustering exists for a number of cancers, including high rates of gastric cancer in Japan and esophageal cancer in southern Africa. Japan's notably high rate of gastric carcinoma (upward of 78 cases per 100,000 people) is thought to be partially attributable to dietary factors, such as consumption of salty, smoked, or pickled foods.²⁵ Interestingly, these high rates drop in Japanese immigrants to the United States. Concomitantly, the rate of colon cancer (typically lower than that seen in the United States) increases to levels comparable to the US-born population within one generation.²⁵ It is hypothesized that at least some of these changes in incidence can be attributed to dietary modifications.

Specific, modifiable dietary factors are difficult to identify. The relationship between nutrition and cancer development is complex, with the epidemiologic studies performed often resulting in conflicting conclusions. The most complete recommendations have been developed by the World Cancer Research Fund in collaboration with the American Institute for Cancer Research. In their publication, they encourage the consumption of a healthy, balanced diet high in fruits and vegetables and limiting the consumption of processed and red meats.²⁶ Fiber has frequently been touted as preventive for the development of colorectal cancer, based on observations that populations with higher overall fiber intake trend toward lower rates of colorectal cancer. This relationship, however, has not been confirmed in the majority of prospective observational and randomized, controlled studies that have been performed to date.^{27,28} As a result, the World Cancer Research Fund and American Institute for Cancer Research consider there to be insufficient evidence to definitively determine whether fiber intake is associated with a decreased risk of colorectal cancer.²⁶ Additionally, data evaluating the importance of other dietary factors, such as carotenoids or vitamins, are considered to be insufficient.

Obesity has been associated with cancer development. Data suggest that esophageal, pancreatic, colorectal, breast, endometrial, and renal cancer may all be increased through obesity or overweight status. Additionally, there is evidence suggesting that increased body weight may also lead to increased mortality associated with a given cancer diagnosis.²⁹ Obesity is therefore one of the most modifiable risk factors for cancer prevention.

Finally, evidence suggests that physical activity is probably effective in protecting against colon, postmenopausal breast, and endometrial cancer.²⁶ There is some uncertainty, however, regarding how this risk factor interacts with other interrelated risk factors, such as obesity or overall healthy lifestyle.

HEREDITARY SYNDROMES

The recent progress in genomic health has led to an increased appreciation of hereditary factors in cancer development. Cancer develops through a variety of genetic mutations that transform a normal cell into a cancer cell. Such mutations may involve pathways that regulate cell replication, apoptosis, and DNA repair. Predisposition to cancer can, therefore, be inherited through mutations in these same pathways, including mutations in proto-oncogenes, tumor suppressor genes, or DNA repair genes. A suggestion of a mutation within a family can typically be identified through a clustering of cancers, with cancers often developing at an unusually early age. Such a history can prompt a referral to genetic counseling for consideration of genetic testing. In other syndromes, cancer is not the most common manifestation of disease, and other signs will be the first to suggest that a hereditary syndrome exists (i.e., neurofibromatosis). A list of common hereditary cancers and syndromes is included as Table 2.

Mutations in tumor suppressor genes are relatively common causes of hereditary cancer development. Cancer development in tumor suppressor genes follows the “two-hit hypothesis,” with a loss or inactivation of both alleles of the gene required to abolish its tumor suppressor function. Patients who inherit a mutation in a tumor suppressor gene require somatic inactivation of the second allele to lead to tumor development. This type of inheritance can be seen with the *RB1* (retinoblastoma) or *APC* (adenomatous polyposis coli) gene. Oncogenes, in contrast, are gain of function mutations; a mutation in a single allele of the associated proto-oncogene is enough to lead to cancer development. Multiple endocrine neoplasia type II develops as a result of an inherited mutation in the *RET* proto-oncogene resulting in the development of medullary thyroid cancer. Finally, cancer can be inherited through defects in DNA repair pathways. DNA repair is vital to the integrity of cells, and failure to faithfully repair DNA breaks may lead to genomic instability, resulting in cancer development. Two best known examples of hereditary syndromes associated with defective DNA repair include hereditary nonpolyposis colon cancer (associated with a defect in mismatch repair genes) and *BRCA1* and *BRCA2* mutations (associated with a number of DNA repair pathways).

Although germline mutations may exist that predispose to cancer development, the true likelihood of cancer is uncertain

Table 2 Common Hereditary Cancer Syndromes⁴⁷

Gene	Type	Locus	Inheritance Pattern	Familial Neoplasm/Syndrome
<i>BRCA1</i>	DNA repair	17q	Autosomal dominant	Hereditary breast and ovarian cancer
<i>BRCA2</i>	DNA repair	13q	Autosomal dominant	Hereditary breast and ovarian cancer
<i>hMSH2</i> <i>hMLH1</i> <i>hPMS1</i> <i>hPMS2</i>	Mismatch repair	2p 3p 2q 7p	Autosomal dominant	Hereditary nonpolyposis colorectal cancer (colorectal, endometrial, brain, urinary tract, other)
<i>NF1</i>	Tumor suppressor	17q	Autosomal dominant	Neurofibromatosis type 1 (neurofibroma, sarcoma)
<i>NF2</i>	Tumor suppressor	22q	Autosomal dominant	Neurofibromatosis type 2 (acoustic neuroma, brain)
<i>RB1</i>	Tumor suppressor	13q	Autosomal dominant	Hereditary retinoblastoma and other second cancers (sarcoma, melanoma, brain tumors)
<i>APC</i>	Tumor suppressor	5q	Autosomal dominant	Familial adenomatous polyposis (colorectal, duodenal, desmoids)
<i>P53</i>	Tumor suppressor	17p	Autosomal dominant	Li-Fraumeni syndrome (sarcoma, breast, brain, leukemia)
<i>MEN1</i>	Tumor suppressor	11q	Autosomal dominant	Multiple endocrine neoplasia type I (pituitary, parathyroid, pancreas)
<i>MEN2A (RET)</i>	Oncogene	10q	Autosomal dominant	Multiple endocrine neoplasia type IIA (medullary thyroid, pheochromocytoma parathyroid)
<i>MEN2B</i>	Oncogene	10q	Autosomal dominant	Multiple endocrine neoplasia type IIB (medullary thyroid, pheochromocytoma, neuromas)
<i>WT1 WT2 WT3</i>	Tumor suppressor	11p	Autosomal dominant	Hereditary Wilms tumor
<i>VHL</i>	Tumor suppressor	3p	Autosomal dominant	von Hippel-Lindau syndrome (hemangioblastoma, renal cell carcinoma)
<i>TSC1, TSC2</i>	Tumor suppressor	9q 16p	Autosomal dominant	Tuberous sclerosis (kidney, brain)
<i>ATM</i>	DNA repair	11q	Autosomal recessive	Ataxia-telangiectasia (breast in heterozygote, lymphoma in homozygote)
<i>PTEN</i>	Tumor suppressor	10q	Autosomal dominant	Cowden disease (breast, thyroid, skin)
<i>STK11</i>	Tumor suppressor	19p	Autosomal dominant	Peutz-Jehgers syndrome (breast, pancreas, hamartomas)

because of variable penetrance. Some syndromes, such as familial adenomatous polyposis, are associated with a 100% risk of developing colorectal cancer by the age of 40; others, such as multiple endocrine neoplasia type II, have a similarly high rate of cancer (medullary thyroid) but present at a much earlier age. Penetrance for all hereditary syndromes is not this complete, however, as cancer development in some syndromes, such as hereditary nonpolyposis colon cancer syndrome, is more variable, and the likelihood of cancer development is much lower.

Prevention

VACCINATIONS

Many infectious agents have been associated with cancer development. In addition to avoidance of these infections through behavioral modifications, vaccination may have an important role in cancer prevention. Two examples where vaccines have been beneficial are hepatitis B virus and HPV. Chronic hepatitis B infection has been associated with the development of hepatocellular carcinoma, increasing it nearly 200 times the population average.¹⁶ Vaccination against hepatitis B reduces an individual's risk of infection and minimizes additional spread of the virus. Hepatitis B vaccination is now offered as part of standard vaccination protocols in the United States for newborns and will likely result in hepatitis B virus being a less frequently associated causative agent for hepatocellular carcinoma in the United States.

HPV is associated with squamous cell carcinoma of the cervix and may have a causative role in squamous cell carcinomas of the head and neck. Two vaccines targeting HPV have been developed and approved by the Food and Drug Administration, the first receiving approval in 2006. Both vaccines target HPV types 16 and 18,^{14,30} with one vaccine additionally covering two HPV strains commonly associated with anogenital warts (types 6 and 11).³⁰ The HPV vaccines have been found to be highly effective at preventing infection, with sustained protection up to 4.5 years after dose administration.³⁰ Importantly, the vaccines have also been found in randomized, controlled trials to be highly efficacious in preventing high-grade cervical intraepithelial neoplasia; two randomized, controlled trials reported 98% efficacy in women who were HPV negative at the initiation of the trial and who completed the vaccination regimen.^{14,15} The bivalent vaccine is currently approved for girls ages 10 to 25 and the quadrivalent vaccine for boys and girls ages 9 to 26. The long-term effect of widespread immunization on cervical cancer incidence and mortality is unknown.

CHEMOPREVENTION

The most successful example of chemoprevention is seen with tamoxifen and raloxifene in women at increased risk for developing breast cancer. Tamoxifen has been most widely evaluated, with several well-designed randomized, controlled trials testing its efficacy in cancer prevention. Overall, the evidence demonstrates that tamoxifen is effective in reducing the risk of breast cancer with a reduction of 38%³¹; these findings are predominantly limited to the prevention of estrogen receptor-positive tumors. Toxicities associated with tamoxifen use include endometrial cancer and an increased

risk of thromboembolic events.³¹ Raloxifene has been tested in postmenopausal women and has been found to be as effective as tamoxifen in reducing the risk of invasive breast cancer (relative risk of 1.02 when compared with tamoxifen).³² However, raloxifene was less successful in preventing in situ cancers (relative risk of 1.4 favoring tamoxifen). Importantly, the toxicity profile of raloxifene differs from that of tamoxifen with fewer cases of endometrial cancer or thromboembolism. Currently, tamoxifen should be considered for chemoprevention in both pre- and postmenopausal women at increased risk for developing breast cancer; raloxifene is an acceptable alternative to tamoxifen for risk reduction in postmenopausal women.

Other examples of chemoprevention include the use of oral contraceptive pills for the prevention of ovarian cancer. This mechanism has been best studied through a collaborative reanalysis of 45 epidemiologic studies of ovarian cancer.³³ Overall, this combined analysis reported a relative risk of ovarian cancer for ever- versus never-users of oral contraceptive pills of 0.73 (95% CI 0.70 to 0.76). There is controversy surrounding the use of oral contraceptive pills as prevention for ovarian cancer, however, given the potential for increased breast cancer rates associated with hormone use. Another class of drugs that have received consideration as chemoprevention agents are the nonsteroidal antiinflammatory drugs (NSAIDs), specifically cyclooxygenase-2 inhibitors. These have been most extensively studied in the prevention of colorectal polyps. Although some data suggest that the use of NSAIDs may decrease the recurrence of colon polyps or decrease the polyp load (especially in high-risk populations),^{34,35} several other studies have not observed an effect.³⁶ Given the mixed results, in combination with the side-effect profile associated with long-term use of NSAIDs, the data cannot currently support the use of NSAIDs as a mechanism of chemoprevention in either the high-risk or general population.³⁶ Finally, a number of studies have evaluated the role of dietary supplements such as retinoids (vitamin A derivatives) or β -carotene but have not identified a clear benefit for cancer prevention associated with their use.²⁴

RISK-REDUCING SURGERY

Risk-reducing surgery is one option patients at increased risk for cancer (most commonly attributable to a genetic mutation) may consider to reduce their risk of developing cancer³⁵; examples where risk-reducing procedures would be considered are listed in Table 3. Patients making decisions for risk-reducing surgery must weigh the benefits associated with reducing their personal risk of cancer development against any potential morbidity or mortality associated with the procedure. Importantly, risk-reducing procedures rarely eliminate all of a patient's future risk of developing cancer. Morbidity associated with risk-reducing procedures may be limited to immediate risks associated with the surgical procedure itself (recurrent laryngeal nerve injury after a risk-reducing thyroidectomy for a patient with multiple endocrine neoplasia type II) or may have longer-lasting implications on overall quality of life (impact on sexuality of bilateral mastectomies for a patient with *BRCA* mutation or bowel function of total proctocolectomy for familial adenomatous polyposis). Each patient's personal decision of whether to undergo such a procedure is complex. It is important to remember that few

Table 3 Risk-Reducing Surgery and Associated Clinical Entities

Clinical Entity	At-Risk Cancer	Risk-Reducing Surgical Procedure	Timing
MEN IIA/B Familial medullary cancer	Medullary thyroid	Total thyroidectomy (with or without central neck dissection and parathyroidectomy)	Based on specific <i>RET</i> mutation (as early as 6 mo of age)
<i>BRCA1/2</i>	Breast	May consider bilateral mastectomies	Anytime
	Ovarian	Recommend bilateral oophorectomy	After childbearing is completed or after age 35
Familial adenomatous polyposis	Colorectal	Recommend total proctocolectomy or total colectomy with ileorectal anastomosis (combined with rectal surveillance)	In teenage years or earlier if polyps have been identified
	Desmoids Upper GI	No recommendation	
HNPCC	Colorectal	Consider total colectomy with ileorectal anastomosis with annual lower endoscopy	Attributable to variable penetrance; no timing recommendation
	Ovarian/Endometrial	No recommendation for risk-reducing oophorectomy or hysterectomy	
Diffuse hereditary gastric cancer	Gastric	No recommendation	
	Breast	No recommendation	
Ulcerative colitis	Colorectal	Consider total proctocolectomy if long-standing active disease	After 10 yr with active pancolitis or in patients with dysplasia
Barrett esophagus	Esophageal	Consider esophagectomy in setting of high-grade dysplasia	Consider after identification of high-grade dysplasia in otherwise healthy patient

HNPCC = hereditary nonpolyposis colorectal cancer; MEN = multiple endocrine neoplasia.

absolute mandates for risk-reducing surgery exist, and the optimal timing for such surgeries is not defined. Alternatives to risk-reducing surgery include chemoprevention in some cases or enhanced surveillance in the hope of detecting a cancer early.

Screening and Early Detection

The primary objective of screening is to identify cancers early (in situ or early stage of disease) when cancers are asymptomatic. This may improve overall outcomes associated with cancer treatment as treatment may be more effective when diagnosed at an earlier stage. However, there are risks associated with screening, and both false negative and false positive results are possible. Guidelines have been created for screening and early detection of common types of cancers; the recommendations from the American Cancer Society are outlined in Table 4.¹³ These recommendations apply to individuals at average risk for developing cancer and not those at increased risk because of family history or environmental exposures.

Mammography is widely recommended as part of breast cancer screening. Currently, the American Cancer Society recommends initiation of screening at the age of 40 for women at average risk for breast cancer.¹³ However, significant controversy has surrounded the age at initiation of screening after the publication of the U.S. Preventative Services Task Force recommendation statement for breast cancer screening in the fall of 2009.³⁷ In this statement, the recommendation was made against routine screening in women aged 40 to 49 who are at average risk for developing

breast cancer. The recommendation was made based on systematic literature reviews, pooled analyses, and models developed by the U.S. Preventative Services Task Force suggesting that the potential harms of screening in this age group (such as false positive findings, unnecessary biopsies, and overtreatment) may outweigh the benefits. However, other societies have interpreted the same data differently and continue to recommend the initiation of screening at the age of 40.¹³ At the current time, it is recommended that the optimal age at which to initiate screening mammography for a woman at average risk for breast cancer should be decided through an informed conversation with that individual's physician. No upper age limit to mammography screening currently exists.

Screening for prostate cancer is equally controversial, and discussions have been ongoing for decades. Two recent randomized, controlled studies evaluating the role of screening for prostate cancer through prostate-specific antigen (PSA) and digital rectal examination have been performed.^{38,39} In both studies, use of PSA blood testing resulted in an increase in the rate of prostate cancer diagnoses. However, it is unclear what the clinical significance of many of these prostate cancers is and whether survival benefit is associated with their early detection. Concerns regarding overdiagnosis and overtreatment of early-stage prostate cancer have made the true benefit of PSA population-based screening uncertain. Current recommendations are for clinicians to initiate discussions regarding prostate cancer screening with patients who can be expected to derive a benefit from treatment of a detected prostate cancer and in whom the benefits of such treatment will outweigh potential risks.⁴⁰

Table 4 American Cancer Society Screening Recommendations for Individuals of Average Risk

Cancer	Screening Modality	Age to Initiate	Frequency
Breast	Mammogram Clinical breast examination Self breast examination	40 20–30 20	Annual Every 3 yr during 20–30s, then annually To be considered
Colorectal	Flexible sigmoidoscopy, or colonoscopy, or DCBE, or CT colonography	50 50 50 50	Every 5 yr Every 10 yr Every 5 yr Every 5 yr
Cervix	Papanicolaou smear	21 or 3 yr after 1st intercourse	Annually until age 30; then may extend screening period based on prior history of normal tests
Prostate	PSA/digital rectal examination	50	Recommend discussion regarding pros and cons of testing
General	Health counseling and physical examination	20	Undefined

CT = computed tomographic; DCBE = double-contrast barium enema; PSA = prostate-specific antigen.

Options for screening of colon cancer have expanded in recent years and include annual fecal occult blood testing, sigmoidoscopy every 5 years, colonoscopy every 10 years, or a double-contrast barium enema every 5 years.¹³ This is recommended to occur beginning at age 50 and continuing until the age of 75. Most recently, virtual colonoscopy (every 5 years) has been included in the recommendations from the American Cancer Society; this recommendation has not been accepted by all organizations, however, in part because of radiation exposure associated with the procedure, cost, and continued requirement for a full bowel preparation.⁴¹

The primary means of screening for cervical cancer remains the Papanicolaou smear. Screening is recommended to start within 3 years after first vaginal intercourse or at the age of 21 and should continue annually until age 30.¹³ After age 30, screening can be tailored for each individual woman, with women who have had three consecutive normal Papanicolaou smears being recommended to either undergo every 2- to 3-year Papanicolaou smears or Papanicolaou smears every 3 years combined with HPV DNA testing. Screening is recommended as long as there is an intact cervix or until the age of 70.

Notably, some common cancers are not included in the screening recommendations. Currently, no recommendation

exists for screening of lung cancer. Early detection of lung cancer is uncommon, and significant attention has been paid toward the development of effective screening regimens. Initial efforts to screen for lung cancer have focused on chest radiographs with sputum cytology. The largest trial was the Mayo Lung Screening Project, a randomized, controlled trial in which chest x-ray and sputum cytology every 4 months over a 6-year period were compared with “usual-care.”⁴² This trial failed to demonstrate a difference in mortality between the trial arms, with a median follow-up time of 20.5 years. More recently, attention has been paid to the utility of helical CT scans. A number of observational trials evaluating helical CT scans have been conducted to date, with a number demonstrating increased detection of stage I lung cancers⁴³; however, limits to the study methodology in the available observational studies, including lead time and overdiagnosis bias, have made it impossible to determine whether early detection of lung cancer translates to any survival benefit.^{44–46} A number of randomized, controlled trials are currently ongoing that will attempt to definitively answer this question.⁴³

27 MOLECULAR GENETICS OF CANCER

Sean Ronnekleiv-Kelly, MD, and Gregory D. Kennedy, MD, PhD

Cancer is responsible for significant morbidity and mortality in the human population. In the United States, there will be an estimated 1.53 million new cases of malignancy in 2010, with approximately 570,000 cancer deaths; the lifetime risk of developing cancer approaches 40%.^{1,2} In the early 1970s, President Nixon declared a war on cancer, and since that time significant resources have been invested in the investigation of the etiology of cancer, including genetic and epigenetic alterations that lead to uncontrolled growth, expansion, invasion, and spread of transformed cells.

Malignancies, either solid tumors or hematopoietic in origin, are fairly rare in younger individuals; the incidence begins to rise exponentially after the age of 30, indicating the contribution of cumulative exposure to environmental carcinogens.³ Additionally, as cancer is fundamentally a genetic disorder, susceptibility also plays an important role. Classification can be generalized by hematologic, which includes leukemia and lymphoma versus solid tumors such as carcinomas and sarcomas.

Regardless of tissue type, the origin of cancer can be simplified by considering the tissue stem cell. In general, undifferentiated stem cells are responsible for generating cellular offspring via division and differentiation. Over a lifetime of environmental exposure, these stem cells and their offspring are vulnerable to transformation from carcinogens.³ In this time interval, alterations of selective genes occur, conferring a growth advantage; this may be either as sequential somatic events generating neoplastic change or as predisposition to familial cancer, in which somatic events are transposed on germline mutations. Somatic accumulation of genetic changes that occur spontaneously is responsible for sporadic forms of cancer, whereas a germline mutation that increases susceptibility to malignant disease is responsible for inherited forms of cancer. Both are discussed in this review.

One of the aims of cancer research is to better understand the etiology of malignancy, resulting in a reduction in incidence and more effective treatment of those with disease. The study of viral pathogens has facilitated elucidation of many aspects contributing toward malignant transformation. These DNA and RNA viruses require the host DNA replication machinery to duplicate its own genetic material. Thus, for their own survival benefit, viruses produce aberrations in growth via persistent induction of the cell cycle, overriding restriction points, abrogating apoptotic signals, and immortalizing the cell, providing limitless replicative potential.⁴

In addition to these qualities, human tumor formation also incorporates ingrowth of vessels to provide nutrients for the rapidly dividing malignant cells, which eventually become invasive and spread to distant organ systems. From this we can see that cancer is likely the result of an accumulation of

genetic alterations in which a stepwise progression of these events ultimately produces unregulated growth and invasion. These changes occur at the molecular level, in which genetic aberrations have been simplified into structural chromosomal alterations, including inversions, deletions, insertions, and amplifications, as well as numerical irregularities, such as losses or duplications of chromosomes.⁵ Unfortunately, these same cytogenetic heterogeneities result in difficulty treating cancer patients as tumors become insensitive to chemotherapeutics as well as radiotherapy treatments.⁶ Thus, knowledge of the precipitating genetic defects in the malignant growth of interest is vital to understanding the basis of cancer formation as well as producing possible treatments to combat the unregulated growth. Tumor formation is inextricably multifaceted, and this accumulation of characteristics underscores the transition from benign cell to malignant entity. This idea is the basis of this review, in which we hope to elucidate the accession of specific critical properties underlying neoplastic transformation.

Cell Cycle

CELL CYCLE BASICS

Cellular interactions constitute a complex network of signaling that mediates normal growth and development. Cells will commit to proliferation (or not) based on the extracellular environment, nutrient availability, growth factor presence or absence, interactions with other cells, and mitogenic signaling.⁷ Intrinsic to this process is cell cycle machinery, and this normally regulated routine occurs aberrantly in malignancy. Usually, a coordinated and supervised cascade of events, with malignant transformation, DNA replication, and cell division, proceeds unmitigated. Given that cancer is a disease of rampant cell proliferation, understanding the cell cycle, including control mechanisms and regulations, is appropriate and is discussed briefly here. A simplified schematic representing the cell cycle is demonstrated in Figure 1.

The basic cell cycle is composed of stages in which the cell coordinates events to promote successful cell division. Included are growth phases, G_1 and G_2 , which occur prior to and prepare the cell for DNA synthesis and mitosis. G_1 phase precedes S phase, allowing preparation of the cell for replication of genetic material. During the S phase, DNA synthesis briefly produces an aneuploid cell with chromosome content between $2N$ and $4N$ but eventually achieves tetraploidy. This is followed by another growth phase in which subsequent M phase or mitosis occurs. Cells that are not cycling are considered G_0 phase.

Figure 1 Simplified schematic of the cell cycle. (a) When prompted via growth factors, increased levels of cyclin D and Cdk4/6 form a complex functioning to promote E2F activity via phosphorylation and inhibition of retinoblastoma, p107 and p130. Activation of E2F results in transcription of numerous genes integral to progression of cell replication including thymidine kinase (TK), DNA polymerase, thymidylate synthase (TS), *c-myc*, dihydrofolate reductase (DHFR), p107, proliferating cell nuclear antigen (PCNA), cyclin E, cyclin A and Cdk2. The cyclin E-Cdk2 complex further stimulates E2F via phosphorylation of pRB; at this point the cycle becomes mitogen independent (cyclin E and cyclin D are main drivers of G₁ to S progression). Also inactivated via phosphorylation are p21 and p27, which are themselves negative regulators of Cdk2 activity. Additionally, the cyclin E-Cdk2 complex targets cyclin E for degradation which allows accumulation of Cdk2, favoring a switch to cyclin A-Cdk2 (a mediator in the DNA synthesis phase). With increased cyclin A-Cdk2 formation, E2F transcriptional activity is prohibited to allow transition into synthesis and subsequently G₂/M. On incurring oncogenic stress, the *INK4a* locus is activated, stimulating expression of p14^{ARF} and p16^{INK4A}. P14^{ARF} then enables p53 to halt cell cycle progression via inhibition of MDM2, a p53 inhibitor protein. In addition, p16^{INK4A} also promotes activity favoring cell cycle cessation via inhibition of pRB inhibitors (cyclin D-Cdk4/6). (b) Cell replication cycle in which the initial growth phase (G₁) proceeds to DNA synthesis (S), followed by a second growth phase (G₂) and subsequent mitosis. G₀ represents a cell that is currently not in cell division. The restriction point (R) represents the period in which withdrawal of growth factors will no longer halt progression from G₁ to S.

Depending on the cell type and growth factor with corresponding receptor, cells can be programmed to undergo differentiation and/or proliferation. For instance, cells residing in the quiescent phase (G₀) can be stimulated to proceed into the first growth phase (G₁) when exposed to various growth factors. These initial promoting proteins include viability factors such as epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and fibroblast growth factor

(FGF). Disruptions of this signal will cause regression to the resting state, whereas subsequent stimulation by complementary factors, such as insulinlike growth factor-1 (IGF-1), will allow continuation through this growth phase and into the synthesis phase (S).^{8,9} In contrast, cytokines such as tumor necrosis factor (TNF) and transforming growth factor-β (TGF-β) may oppose these proliferative effects, even late in the growth phase.¹⁰

REGULATORY OVERVIEW

There are two main types of cell cycle regulation, including a highly selective cascade of protein phosphorylation and cell cycle checkpoints; both ensure appropriate completion of necessary events prior to enabling progression to the subsequent stage.¹¹ The first regulatory mechanism implements kinases that relay information via phosphorylation. These kinases (cyclin-dependent kinases or CdKs) interact with their partner cyclin proteins and use adenosine triphosphate (ATP) to phosphorylate specific amino acid residues on target proteins. In addition, binding of cyclin to its respective CdK localizes the complex, where its functions are completed.⁴ Through highly coordinated expression and degradation profiles, the cyclins promote activity at specific time points, allowing for synchronized progression through the cell cycle.

The transition from G₁ to S phase appears to be a site of significant regulation and is contingent on many proteins, including cyclins, CdKs, retinoblastoma-susceptibility tumor suppressor protein (pRB), and p53 [see Figure 1].^{3,12} When growth factors stimulate the cell to proliferate, D-type cyclins detect these extracellular mitogenic cues and bind to CdK4 and/or CdK6. The cyclin-CdK complex is then phosphorylated by CdK-activating kinase (CAK), which enables the complex to promote progression of the cell from G₁ phase into S phase.¹² Notably, these D-type cyclins, such as cyclin D₁, turn over rapidly, with a half-life of approximately 15 minutes. The presence of mitogens stabilizes their expression. Conversely, loss of mitogenic stimuli prior to S phase results in rapid degradation of these regulatory proteins and return of the cell to a quiescent state.¹³

In addition to external stimuli, cyclin and CdK activity can also be regulated by the intrinsic CdK inhibitors. These inhibitors allow for cells to arrest in G₁, thereby enabling the repair of DNA damage, terminal differentiation, and cell senescence. The two major families of CdK inhibitors are Cip/Kip and inhibitors of CdK4 (INK4). Members of the Cip/Kip family include p21^{Cip1}, p27^{Kip1}, and p57^{Kip2}. These proteins bind and act as negative regulators of cyclin E- and cyclin A-CdK2 and cyclin B-CdK1 in a 1:1 stoichiometry.¹⁴ Additionally, the Cip/Kip family members also act as positive regulators of cyclin D-CdK4/6 complexes by mediating their assembly early in G₁.¹⁵ This early assembly results in the titration of p27^{Kip1} from and activation of the cyclin E-CdK2 complex. As a result, p27^{Kip1} is phosphorylated and degraded, thereby enabling the cell to progress through the cell cycle. In contrast, the INK4 family members directly compete for binding to CdK4/6 with the D-type cyclins.^{3,13,16-19} Forced expression of INK4 proteins can lead to G₁ arrest by promoting the redistribution of Cip/Kip proteins and the inhibition of cyclin E-CdK2 activity.

At the restriction point, progression through the cell cycle becomes mitogen independent and proliferation continues despite removal of growth stimuli.¹³ Phosphorylation by CdK4 of the target protein pRB allows desequestration of the E2F family of transcriptional regulators, which stimulates transcription of DNA sequences that form numerous proteins integral to the synthesis phase of cell replication.³ The significance of cyclin-CdK involvement in cell proliferation and tumorigenesis is emphasized by the finding that dysfunction of CdK activity is found in the majority of human tumors.⁷ Once deregulation occurs, the presence or withdrawal of

growth factors no longer dictates the cascade progression, and the cell is continuously coerced to replicate.

Ensuing progression through the cell cycle is regulated by several factors. However, this process can be considered to be the result of forward progress mediated by the expression of proteins responsible for increasing the expression of protein kinases responsible for driving the cell cycle. Alternatively, the lack of progress can be secondary to the identification of errors in the DNA that have accumulated in the S phase.

Retinoblastoma

Retinoblastoma protein exerts most of its influence in the first two thirds of G₁ phase, integrating various upstream signals and ordaining the fate of the cell with regard to progression into synthesis phase. The upstream determinants include growth factors and mitogens, which function to ultimately inhibit pRB via phosphorylation, as well as growth inhibitors, which act to maintain pRB in its hypophosphorylated state.¹³ When hypophosphorylated, pRB forms a stable, intracytoplasmic complex with the E2F proteins, suppressing their ability to form the necessary protein-protein interactions and DNA binding requisite for transcriptional activation.^{13,20} The E2Fs are a family of heterodimeric transcription activators, including E2F-like and DP-like subunits.²¹ Phosphorylation of pRB reverses the growth inhibitory effect as E2Fs are released, translocate to the nucleus, bind to DNA, and mediate transcription of several proteins integral to S-phase entry.^{18,22} In addition, E2F promotes expression of itself through a positive feedback loop, as well as cyclin E and CdK2, further perpetuating cell proliferation via phosphorylation of pRB [see Figure 1]. Progression of the cell beyond this point and into S phase does not rely on cyclin D-CdK4 but rather is driven by cyclin E-CdK2 in a mitogen-independent fashion.^{3,13} In conjunction, beyond the restriction point, the phosphorylation state of pRB becomes less relevant to progression into S phase.

Cyclins-CdKs

Multiple cyclin-CdK complexes are activated as the cell navigates the replicative cycle, often with overlapping substrate preferences [see Figure 2]. The expression levels of these complexes vary with the cycle stage, resulting in intricate interplay guiding the cell in its division. In human cells, cyclin D binding to CdK4/6 and cyclin E binding to CdK2 are essential and rate-limiting steps commencing E2F-dependent transcriptional activity (via phosphorylating pRB, p107, and p130) and transitioning into S phase.⁷ When signaled to proliferate, the cyclin D-CdK4/6 complex is phosphorylated and activated and consequently abrogates the inhibitory effect of pRB, p107, and p130. Subsequently, E2F responsive promoters are then disinhibited, with resultant transcription of numerous genes, among which are cyclin E and cyclin A₂. With accumulation of cyclin E bound to CdK2, the cell passes the restriction point, entering S phase, and is destined for cell division. Once synthesis of DNA (replication) has begun, progression through S phase is coordinated initially by cyclin E-CdK2, followed by cyclin A-CdK2 activity. This transition is coordinated by cyclin E-CdK2, which is responsible for the phosphorylation of cyclin E, leading to its degradation and subsequent accumulation of available CdK2, favoring a switch to the cyclin A-CdK2 complex. The cyclin

Figure 2 Cyclin-Cdk complex function during the cell cycle. On stimulation by various growth factors (large black arrow), upregulation of cyclin D (CyD) and Cdk4/6 results in the formation of cyclin D₁-Cdk4/6 complex. Subsequent phosphorylation of protein RB (pRB) allows desequestration of E2F and ensuing transcription of cyclin E (CyE), cyclin A (CyA), and Cdk2. Cyclin E binding to Cdk2 forms a complex that functions to further phosphorylate pRB. This releases the cell from growth factor dependence as the cell passes the restriction point (R) and becomes mitogen independent. The cell proceeds into DNA synthesis phase directed by cyclin A-Cdk2 as cyclin E is phosphorylated and targeted for degradation. Cyclin A-Cdk2 inhibits E2F promotion of transcription (small black arrow), allowing transition to the DNA synthesis phase. Cyclin A is prominent during G₂ phase as well but partners with Cdk1 during the second growth period. Finally, cyclin B (CyB)-Cdk1 promotes mitosis and cell division. Proteasome-mediated cyclin B degradation leads to exit of mitosis and reentry into G₁ (gray arrow).

A-Cdk2 complex in turn sequesters E2F, thereby blocking its DNA binding domain and effectively decreasing the E2F-responsive genes, a step integral toward the advancement of synthesis and subsequent entry into the second growth phase. Progression through G₂ remains similarly dependent on cyclin A. However, mitosis and cell division appear to be dependent on cyclin B-Cdk1 activity.⁷ Late in this final phase, proteasome degradation of cyclin B (with inactivation of respective Cdk1) allows completion of mitosis and ingress into G₁. Thus, through the coordinated effort of cyclins and their respective kinases, E2F activity is enhanced, perpetuated, and extinguished at appropriate time points.²¹ Interestingly, however, there is significant overlap and redundancy of these proteins such that knockout or inhibition of cyclins or respective kinases can still produce effective cell growth and proliferation.⁷ The implications of this overlap with respect to malignant transformation indicate that targeting this pathway with cancer therapeutics may prove difficult with such redundancy as tumor cells may “escape” via numerous mechanisms.

Cdk-cyclin activity is dependent on the heterodimerization and nuclear translocation of the complex; in contrast, phosphorylation of the individual subunits targets them for degradation.⁷ Alternatively, the activity of the Cdk-cyclin complexes can also be regulated by Cdk inhibitors, such as the INK4 family. Within the INK4 family are p15, p16, p18, and p19, all of which bind Cdks and form stable complexes at remote binding sites to effectively decrease cyclin heterodimerization, thereby facilitating its degradation.⁴ For example, p16, transcribed from the *INK4A* locus, is a critical regulator of pRB and has been shown to be involved in the inhibition

of the cyclin D-Cdk4/6 complex.²³ This unique locus also contains a second overlapping gene that is generated via an alternative reading frame (first exon 1 α versus 1 β with common downstream exons) from a separate promoter. The 1 α transcript is processed into p16^{INK4a}, whereas the 1 β reading frame is processed into a 14 kDa protein known as p14^{ARF} (ARF or alternative reading frame).²⁴ p14^{ARF} also participates in cell cycle regulation by inhibiting MDM2, the protein responsible for the degradation of p53.²⁵

p53

The second category of regulation involves checkpoints responsible for the propagation of “pure” genetic information. Activation of the checkpoint proteins blocks cell cycle progression, thereby preventing the replication or segregation of dysfunctional DNA.¹¹ These superimposed controls are not essential to the underlying workings of the cycle; however, they impede progression when stressors elicit DNA damage and allow repair to maintain genomic integrity. One such extensively investigated checkpoint regulator is p53, which stabilizes and accumulates in response to DNA damage.³ Remarkably, in addition to binding of specific sequences, p53 can recognize and bind multiple types of DNA damage such as breaks (free DNA ends), single-stranded DNA, and insertion or deletion mismatches.⁴ On survey and identification of damage to genetic material, p53 enlists various proteins via its transcriptional activator mechanism to delegate appropriate responsibilities. Among the most important genes promoted from transcriptional activation is *p21^{Cip1}*. This protein functions to arrest the cell by inhibiting cyclin-Cdk activity (specifically cyclin E-Cdk2 and cyclin A-Cdk2), resulting in the accumulation of hypophosphorylated pRB and inactivation of E2F.²⁶ In contrast to the INK4 family of inhibitors (which bind allosteric sites), however, inhibition by p21^{Cip1} can be overcome by elevated concentrations of cyclins.⁴

Like many cell cycle regulatory molecules, p53 regulates its own expression. One such regulatory mechanism involves increasing the expression of the MDM2 protein. MDM2 inhibits p53’s function by both blocking its ability to mediate transcription and serving as a ubiquitin ligase mediating p53 degradation.²⁷ Feedback inhibition is important to allow reentry into the cell cycle when damaged DNA is no longer present.

Although integral, p21-regulated inhibition is not the solitary function of p53. With the accumulation of an unsustainable number of deformations, p53 is also responsible for inducing cell suicide or apoptosis. This complex mechanism is achieved via increased expression of apoptosis inducers such as the *Bax* gene, which uses the intrinsic programmed cell death pathway to direct cell destruction [see Evading Apoptosis, below]. Given that the propagation of a significantly altered genome may have deleterious consequences to the organism, an option to eradicate such material would be advantageous. In fact, the apoptotic pathway is perhaps the most potent defense mechanism retarding cancer in that pre-malignant cells are destroyed prior to replication of toxic genetic material. Thus, whether instructing self-sacrifice as a result of dangerous levels of genotoxic damage or restoring DNA integrity to baseline, p53 has the extraordinary capability to assimilate input from multiple sources, integrate the

variegated signals, and coordinate the most appropriate response. Regrettably, because of its indispensable nature in ensuring genome stability, the gene is often mutated in malignant disease, with most modifications occurring in the DNA-binding domain, debilitating the protein's competency in transcriptional stimulation.²⁶

Primary Characteristics

Normal proliferation of a cell is a calculated balance between signals that promote and signals that inhibit growth. By definition, a cancer cell possesses all of the necessary components of cell growth, allowing it to proliferate indefinitely. Considering the number of distinct forms of malignancy, each with unique mechanisms to propagate survival, the concept of a shared progression of identical events seems unlikely. However, despite the unique genetic alterations that accompany any given cancer, the consequential change in fundamental processes appears to be distributed to all malignant growths. The end result encompasses adaptations characterized by continuous growth signaling, insensitivity to growth inhibition, evasion of apoptosis, angiogenic potential, immortalization, and invasion or metastasis. These changes leading to invasive cancer were elegantly described in 2000 by Hanahan and Weinberg.²⁸ The majority of this chapter is dedicated to reviewing these traits of cancer as defined by these authors.

Among the early transformations that occur as a cell traverses the expanse from benign to malignant disease are self-sufficiency in growth signals and insensitivity to growth inhibitory signals. Throughout the literature, the genes responsible for these phenotypes are classified as oncogenes and tumor suppressor genes. Regardless of the nomenclature, the significance of each is that one is considered a dominant mutation, whereas the other contributes to neoplastic transformation in recessive form. Self-sufficiency of growth signals may occur via a variety of mechanisms, including point mutations, chromosomal juxtapositions, insertions, and deletions; the result is a dominant form of disease such that a single allele need only be affected.²⁹ In contrast, insensitivity to growth inhibitory signals contributes to oncogenicity via inactivation of both alleles, indicating recessive behavior. Also deemed loss of heterozygosity (LOH), this may occur via loss of a gene, a region of a chromosome, or an entire chromosome. Illustrative of early events occurring in transformation are colon biopsy specimens in which adenomas carry a mutation activating the oncogene *K-ras*, whereas evolution into invasive carcinoma is associated with loss of the deleted in colon carcinoma (*DCC*) tumor suppressor gene and the *p53* tumor suppressor gene.³⁰

Although self-sufficiency in growth signaling and loss of growth inhibition are likely early events in malignant transformation, it is difficult to state with certainty when the complementary events occur within the spectrum of benign to malignant disease and in which sequence. For instance, a cell may suffer an activating mutation of an oncogene followed by LOH of the tumor suppressor gene *p53*, thereby overcoming growth inhibition and programmed cell death. The instability created may then predispose to recruitment of new blood vessel formation and limitless replication, with subsequent

invasion and metastasis. Regardless of succession, each characteristic is quite essential to the final product, which is the complex malignant disease known as cancer.

SELF-SUFFICIENCY IN GROWTH SIGNALS

Cells require a carefully orchestrated series of events to produce the signaling pathways that promote growth and proliferation. Growth factors bind receptors that convey the information to a multitude of intracellular proteins and, ultimately, alter DNA transcription and synthesis [see Figure 3]. Similar to other processes regulated within the cell, expression of these proto-oncogenes is carefully controlled to prevent aberrant growth signaling. Unfortunately, alterations of these genes result in a dominant phenotype recognized as gain-of-function mutations, and these lesions were the first genetic changes shown by investigators to promote cancer development.⁸ Thus, a cell may become independent from exogenous stimulation via alteration of ligands, the respective receptors, or intracellular targets. The resulting downstream effects of these transformed growth signaling proteins result in activation of signal transduction pathways that ultimately stimulate cell growth and proliferation. The genes involved are referred to as oncogenes. Interestingly, many different oncogenes may have the ability to promote growth signaling in any one specific tumor, suggesting redundancy in function; in contrast, a single oncogene may have this growth-promoting effect in another tumor type, indicating specificity.

Activation of an oncogene may occur via a number of mechanisms, including alterations to the gene itself, such as point mutations, deletions, or insertions, or from reformation in the promoter region, resulting in increased transcription. Additionally, gene amplification can produce increased chromosomal number, whereas translocations can enhance expression of key proliferative genes or generate unique constitutively active fusion proteins [see Figure 4]. Regardless of the mechanism, the result is deregulation of the oncogene. This deregulation, in combination with additional alterations of normal cell function, results in malignant transformation. Consistent with the multitude of growth stimulatory pathways, there are numerous recognized oncoproteins involved in mitogenic signal transduction. These include secreted growth factors, the respective growth factor receptors, proteins responsible for cytoplasmic signal transduction, and transcription factors.⁴ Table 1 displays a nonexhaustive list of oncogenes involved in malignant transformation.

Growth Factors and Growth Factor Receptors

The discovery of human receptor tyrosine kinases (RTKs) can be traced to early investigations into the functions of retroviral oncogenes.⁸ These receptor kinases resembled their viral counterparts in that the human homologues autophosphorylated tyrosine residues, which activated downstream signaling.⁸ For instance, the viral *src* gene encodes a kinase that phosphorylates tyrosine residues and has sequence similarity to the v-erb-B transforming protein (avian erythroblastosis virus), which is a truncated form of the human epidermal growth factor receptor (EGFR).³¹ Additionally, the viral-*sis* oncogene (simian sarcoma virus) is structurally similar to the β -chain of platelet-derived growth factor (PDGF- β).^{6,32} Therefore, this striking discovery of sequence

Figure 3 Growth factor binding receptor. Transforming growth factor- α (TGF- α) binds epidermal growth factor receptor (EGFR), which induces conformation change and subsequent receptor dimerization (or oligomerization) with transphosphorylation of tyrosine residues in the intracellular domain. Receptor phosphorylation recruits downstream signaling molecules such as Src, phosphoinositide-3-kinase (PI3K), phospholipase C (PLC- γ), Grb2, Shc, and Cbl. Propagation of signaling (i.e., from Grb2 to Ras) ultimately produces changes in gene expression favoring cell growth and proliferation.

Figure 4 Mechanism of oncogene production. Activation of proto-oncogenes occurs in a dominant fashion. Point mutations, deletions, or insertions in the gene can lead to altered protein products that result in exaggerated activity in the presence of ligand or constitutive activation. Additionally, mutations in the promoter region may enhance transcription of the gene, whereas gene amplification can produce multiple gene copies, ultimately increasing the amount of proto-oncogene present in the cell. With translocations, promoters from a different chromosome region that are perpetually active may be aberrantly inserted upstream of the proto-oncogene. Again in conjunction with translocations, the resultant gene product may form a chimeric fusion protein that is no longer dependent on ligand binding or upstream signaling; instead, it is constantly activated.

Table 1 Nonexhaustive List of Oncogenes in Human Malignancy

Gene	Gene Product	Oncogene Mechanism	Cancer Association
<i>erb-B1</i> (EGFR/HER-1)	EGFR family RTK	Amplification, overexpression	Squamous cell carcinoma, glioblastoma
<i>erb-B2</i> (HER-2/ <i>neu</i>)	EGFR family RTK	Overexpression	Breast, stomach, ovary, lung adenocarcinoma
<i>Met</i> (HGFR)	HGFR RTK	Amplification, overexpression	Gastric, renal cell carcinoma
<i>Bek</i> (FGFR2)	FGFR RTK	Amplification, overexpression	Gastric, endometrial, lung, breast, ovarian cancer
<i>Ret</i>	GDNF family RTK	Point mutations, translocation	PTC; MEN IIA/IIB (familial), MTC (familial)
<i>K-ras</i>	Guanosine triphosphatase	Point mutations	Lung, colon, pancreatic, and other carcinoma
<i>N-ras</i>	Guanosine triphosphatase	Point mutations	AML, MDS
<i>B-Raf</i>	Serine/threonine kinase	Point mutations	Melanoma, CRC, HCC
<i>c-myc</i>	Transcription factor	Translocation, amplification, overexpression	NB, SCLC, B/T cell lymphoma, breast, esophageal, cervical, ovarian, head/neck cancer
<i>N-myc</i>	Transcription factor	Amplification	NB, SCLC
<i>L1-myc</i>	Transcription factor	Amplification	Ovarian cancer, SCLC
<i>CDK4</i>	Cyclin-dependent kinase	Amplification	Gliomas, sarcomas
<i>CycD1</i>	Cyclin D ₁	Translocation, amplification, overexpression	SCC head/neck, B cell lymphoma, SCLC, HCC, CRC, esophageal, bladder, breast cancer, sarcoma, melanoma
<i>MDM2</i>	p53 inhibitor	Amplification, overexpression	Sarcoma
<i>Cdc25b</i>	M-phase inducer phosphatase	Overexpression	Breast cancer
<i>Notch</i>	Surface receptor, transcription activator	Point mutations, translocation	T cell ALL
<i>Bcr-abl</i>	Chimeric constitutively active non-RTK	Translocation	CML, ALL, AML
<i>Alk-NPM1</i>	Chimeric TK	Translocation	Anaplastic large cell lymphoma
<i>NUP214-Abl1</i>	Chimeric TK	Translocation	ALL
<i>Runx1-Runx1tl</i>	Chimeric transcriptional repressor	Translocation	AML
<i>F111-EWSR1</i>	Chimeric transcriptional activator	Translocation	Ewing sarcoma
<i>Pml-RARA</i>	Chimeric transcriptional repressor	Translocation	Acute promyelocytic leukemia
<i>TMPRSS2-ERG</i>	Chimeric transcriptional promoter	Translocation	Prostate cancer

ALL = acute lymphoblastic leukemia; AML = acute myelogenous leukemia; CML = chronic myelogenous leukemia; CRC = colorectal cancer; EGFR = epidermal growth factor receptor; FGFR = fibroblast growth factor receptor; GDNF = glial cell line-derived neurotrophic factor; HCC = hepatocellular carcinoma; HGFR = hepatocyte growth factor receptor; MDS = myelodysplastic syndrome; MEN = multiple endocrine neoplasia; MTC = medullary thyroid cancer; NB = neuroblastoma; PTC = papillary thyroid cancer; RTK = receptor tyrosine kinase; SCC = squamous cell carcinoma; SCLC = small cell lung cancer; TK = tyrosine kinase.

homology between viral proteins with transforming capability and analogous human proteins facilitated the delineation of human proto-oncogene function. This distinction enabled a better characterization of mitogenic signaling and its implications.

The succession of events from binding of extracellular growth factor to DNA transcription is tightly regulated within the normal cell. Generally, the source of mitogenic growth factors arrives from another cell such that the proliferative fate is governed by exogenous signals.²⁸ Certain malignancies, however, have exploited this pathway via continuous generation of growth factors. For example, this level of regulation is

circumvented in sarcomas and breast cancer, in which autosecretion (autocrine stimulation) of transforming growth factor- α (TGF- α) allows persistent growth signaling on binding to EGFR.^{28,33} Receptors such as EGFR are transmembrane RTKs with intrinsic kinase capabilities (various transmembrane tyrosine kinases are depicted in Figure 5). When the growth factor ligand binds its corresponding receptor, a conformational change of the transmembrane receptor is induced, with resultant dimerization or oligomerization leading to activation of the kinase domain.

Subsequently, transphosphorylation of tyrosine residues in the cytoplasmic domain results in transduction of the

Figure 5 Various transmembrane tyrosine kinases. The receptor names are listed below with the designated ligands above. Each receptor has a conserved tyrosine kinase (TK) domain. On ligand binding, these receptors dimerize and subsequently transphosphorylate the intracellular domain. This allows recruitment of downstream signaling molecules. aFGF = acidic fibroblast growth factor; bFGF = basic fibroblast growth factor; EGF(R) = epidermal growth factor (receptor); FGFR = fibroblast growth factor (receptor); HGF(R) = hepatocyte growth factor (receptor); PDGFR = platelet-derived growth factor (receptor); PIGF = placental growth factor; TGF = transforming growth factor; VEGF(R) = vascular endothelial growth factor (receptor).

mitogenic signal via interaction with intracellular proteins.^{6,33,34} For instance, the EGFR family is composed of four receptors, including erb-B1 (EGFR/HER1), erb-B2 (HER2/neu), erb-B3 (HER3), and erb-B4 (HER4). With binding of complementary ligand (i.e., TGF- α), the sequence of events causing autophosphorylation of the cytoplasmic domain then enables propagation of the growth signal via multiple effector proteins, such as Src, phosphoinositide-3-kinase (PI₃ kinase), phospholipase C (PLC- γ), STATs, Grb2, Shc, and Cbl [see Figure 3].³³ Similarly, when PDGF binds its receptor (PDGFR), phosphorylation of the intracellular portion with consequent kinase activation recruits various intracellular proteins such as PLC- γ , PI₃ kinase, Ras guanosine triphosphatase (GTPase), Ras GTPase activating protein (GAP), and Src.⁸

Deregulation of these growth factor receptors can occur through many genetic events, including amplification, deletion, and truncation. Such deregulation can result in constitutive activation in the absence of ligand stimulation.³⁴ The favorable proliferative phenotype manifest by transformation of the RTKs justifies why this is a relatively common theme throughout cancer biology. Specific examples include erb-B2-4 seen in lung cancer, HER2/neu in breast cancer, and Kit mutation in gastrointestinal stromal tumors (GISTs), all of which are within the EGFR family.⁶ These modified proteins continuously transmit proliferative signals via their intrinsic signaling pathways. Vascular endothelial growth factor (VEGF) is another ligand, the effects of which are mediated by three RTKs: VEGFR1 (FLT 1), VEGFR2 (KDR/FLK1), and VEGFR3 (FLT4). This ligand-receptor pair is responsible for stimulation of angiogenesis in a number of malignancies and thus has become a target for chemotherapeutics [see Angiogenesis, below].

Notable for its role in familial syndromes of endocrine neoplasms, *Ret* encodes an RTK expressed in neural crest-derived and urogenital cells that is integral to normal development in cell lines of the peripheral nervous system (including the enteric nervous system), kidney morphogenesis, and spermatogenesis.³⁵ This receptor binds growth factors of the glial cell line-derived neurotrophic factor (GDNF) family in the presence of GDNF-family receptor- α (GFR- α) proteins. On ligand binding, the Ret receptor dimerizes and subsequently autophosphorylates its tyrosine residues, allowing for the propagation of the signal along its transduction pathway.³⁵ This growth signal is transmitted via the Ras/extracellular signal-related kinase (ERK) or PI₃ kinase-Akt pathway.³⁵ Somatic rearrangements of the *Ret* gene, which can be induced by ionizing radiation, lead to ligand-independent activation, as seen in papillary thyroid cancer.³⁶ In addition, germline point mutations in *Ret* result in autosomal dominant multiple endocrine neoplasia (MEN) types IIA and IIB and familial medullary thyroid carcinoma (FMTC).³⁷ These mutations in the *Ret* gene result in constitutive dimerization and activation of the receptor with persistent transmission of growth signals, giving the cells a genetic predisposition to malignancy.³⁵

From the establishment of growth signaling pathways and elucidation of aberrancies intrinsic to cancer, novel targeted therapeutics have been developed that specifically inhibit activity in select cancers. This is in contrast to various forms of chemotherapeutics, which generally target rapidly dividing cells. The strategy of implementing targeted molecules to combat the molecular alterations in cancer is frequently used when receptor activation is the underlying etiology of a sustained promotion of growth signals. Bevacizumab is a recombinant humanized monoclonal antibody that binds

soluble vascular endothelial growth factor A (VEGF-A), preventing receptor binding (VEGFR). This agent has been approved for use in colorectal cancer as well as non-small cell lung cancer and is currently being investigated in a variety of other cancers, including renal cell and ovarian cancer and glioblastoma.^{6,38}

Another drug within the antiangiogenic class is the tyrosine kinase inhibitor (TKI) SU5412 (sunitinib), which binds the intracellular RTK of VEGFR1 and R2, as well as PDGFR and Kit. When bound by SU5412, the transmission of growth signals by the VEGFR is blocked. SU5412 has been shown to be effective in GISTs and renal cell carcinomas.^{6,39}

Other targeted therapies that have been developed include cetuximab, erlotinib, and gefitinib. Cetuximab is a chimeric IgG1 monoclonal antibody directed against the extracellular, ligand-binding domain of the RTK EGFR.⁴⁰ Cetuximab is used in irinotecan-resistant metastatic colorectal cancer, advanced squamous cell cancer of the head and neck, and advanced non-small cell lung cancer.^{6,40,41} Erlotinib and gefitinib are small molecule inhibitors of the intracellular kinase domain that are used in non-small cell lung cancer.^{6,41} Trastuzumab is a monoclonal antibody directed against the HER2/neu RTK in breast cancer and was found to reduce the rate of death when implemented as adjuvant therapy for primary cancer and in metastatic disease.^{6,42}

Since the inception of cancer-directed treatment, there has been an expansion in the number of therapeutic agents available, each exploiting mechanisms used by cancer to sustain growth. These few examples are among the remarkable targeted therapies that represent the novel strategies recently implemented as a result of the intensive investigation delineating essential pathways in cancer genetics.

Intracellular Targets

The complexity of the intracellular compartment is astounding. Numerable interactions between immense numbers of proteins compound the difficulty in understanding sequential events that occur within the cell. As multiple signaling pathways comprise the internal circuitry of a cell, tumor cells incorporate several strategies to achieve self-sufficiency in growth signaling. As a result, substantial volumes of information could be included in the following section. However, the discussion here includes various intracellular proteins common to cancer and those involved in unique genetic interactions, such as translocations and fusion proteins.

Central to many of the growth factor receptor (GFR) pathways, as well as various cytokines and integrin signaling, Ras is altered in approximately one fourth of malignant tumors.²⁸ As demonstrated in Figure 3, with binding of growth factor to GFR, activation of multiple intracellular targets occurs. One such protein is Grb2 (or SOS), which can then activate Ras. Activation of Ras triggers phosphorylation of Raf kinase, which phosphorylates the mitogen-activated protein kinases (MAPKs) MEK1 and MEK2 (mitogen-activated protein ERK kinase); this signal is transduced to erk-1/2, which dimerizes and localizes to the nucleus to stimulate cellular proliferation.³⁸ Activating mutations in *Ras*, found in many cancers, including colon, pancreatic, and ovarian cancers, triggers this cascade independent of upstream regulation, rendering the cell in a constant proliferative state.³⁸ Additionally, mutated *Ras* has been found to be a poor prognostic indicator

in colon cancer.⁴⁰ In an attempt to interrupt the constitutively active cascade, a specific intracellular TKI, AZD6244, was developed that functions to bind the tyrosine kinases MEK-1/2. Trials with this agent have completed phase II in ovarian adenocarcinoma and are examples of strategies that can be used on discerning underlying disease mechanism and pathways.³⁸

Upregulation of various cyclins and their kinases is a common mechanism in malignancy as they are directly involved in cell cycle progression.³ For instance, cyclin D₁, which functions to inhibit pRB in response to growth signaling [see Cell Cycle, above], is amplified or overexpressed in many different malignancies [see Table 1]. In B cell lymphomas, an immunoglobulin heavy chain enhancer is translocated into the cyclin D₁ locus, resulting in increased synthesis.²³ In a transgenic mouse model, overexpression of cyclin D₁ in mammary epithelial cells induces mammary tumor formation, whereas nullizygous mice demonstrate deficits in breast development (despite normal hormone levels). Results such as these not only emphasize the importance of cyclin D₁ in normal cell growth and development but also demonstrate that dysregulation can result in a malignant phenotype.^{43,44}

The discovery of perhaps the best known oncogenic intracellular signaling molecule stemmed from the detection of a transforming sequence of the MC29 avian tumor virus that resulted in a form of leukemia called myelocytomatosis and thus was labeled *Myc*.⁴⁵ Interestingly, the discovery of this gene and ensuing studies regarding its involvement in cancer led to the realization that neoplastic transformation could occur in the absence of gene mutation. Instead, *Myc*, a nuclear phosphoprotein that functions as a transcriptional regulator of many genes involved in proliferation, differentiation, angiogenesis, and apoptosis, is activated via chromosomal translocation, gene amplification, or insertional mutation [see Figure 6].⁴⁵ In Burkitt lymphoma, Ig heavy and light chains (constitutively active in B cells) located on chromosome 14, 2, or 22 are translocated to chromosome 8 adjacent to the *Myc* locus, thus resulting in unregulated expression and cell proliferation.^{29,45}

Although translocation appears to be the aberration in hematogenous malignancy, amplification is the method of activation in solid tumors. Amplification of *N-Myc*, a gene usually expressed during development, was seen in neuroblastoma tumor samples and corresponded with older age at onset and later stage at presentation, portending a poorer prognosis.⁴⁶ Furthermore, amplification of either *Myc*, *N-Myc*, or *L1-Myc* was found to be a common genetic abnormality in small cell lung cancer.⁴⁷ In addition to revealing a new genetic anomaly in cancer cells, another important aspect of *Myc* investigation that advanced the understanding of neoplastic transformation involved cooperativity studies in which immortalization of cell lines did not occur unless *Myc* was paired with another oncogene, such as *Ras*.⁴⁸ These studies contributed to the basis for a multistep model in tumorigenesis.

An important regulatory protein that was also initially found to be involved in hematopoietic malignancy is Notch. Notch is a family of transmembrane proteins that, when bound by ligand, lead to an intracellular cascade of events. There are four transmembrane Notch receptors (Notch1 to Notch4), as well as five transmembrane ligands (jagged-1

Figure 6 In Burkitt lymphoma, Ig heavy and light chains are translocated adjacent to the *Myc* locus on chromosome 8. These promoters are normally constitutively active and upon translocation, *c-myc* becomes deregulated. Additionally, *c-myc* may demonstrate enhanced activity thus promoting proliferation, angiogenesis and inhibition of apoptosis via amplification or point mutation. Chromosomal translocation t(7;9), in which the T cell receptor- β (*TCR-b*) promoter/enhancer is transposed next to a truncated form of *Notch1* (intracellular Notch [*icN*]), results in constitutive expression of *icN*. In addition, point mutations in the heterodimerization or proline, glutamine, serine, threonine-rich (PEST) domain both lead to increased Notch activity.

[JAG1], jagged-2 [JAG2], delta-like-1 [Dll1], Dll2, and Dll4), and the Notch cell-cell signaling pathway is expressed in most cells.⁴⁹ Subsequent to ligand binding, cleavage of Notch receptor via tumor necrosis factor- α converting enzyme (TACE) and presenilin (γ -secretase) releases the intracellular domain of Notch (*icN*).^{49–51} Nuclear translocation of *icN* allows formation of a coactivator complex with other binding proteins (CBF1/Su(H)/LAG1 or collective CSL complex), resulting in a potent transcriptional activator of various growth-promoting genes.⁵²

Crucial for cell signaling, normal development, and cell fate determination of adjacent cells via lateral communications, Notch also contributes to the malignant phenotype in many different cancers.⁵³ Its role in cancer was discovered from investigation of leukemia, in which overexpression of *icN* was driven via a t(7;9) translocation, juxtaposing *Notch* with the constitutively active T cell receptor- β enhancer.^{29,53} Despite its discovery of deregulation via translocation, activating point mutations in various domains are the much more common etiology resulting in dysfunction and are present in more than half of all T cell acute lymphoblastic leukemias [see Figure 6].⁵⁴ The findings of aberrant Notch activation and deregulated *Myc* activity (discussed above) are examples of the various methods in which growth advantage may be conferred (i.e., translocation, amplification, point mutation), and their investigation has allowed better understanding of the tumor model.

Notable for the first consistent chromosomal abnormality identified in patients with cancer, the Philadelphia chromosome is a t(9;22) translocation involving the *Bcr* gene (intracellular signaling molecule involved in phosphorylation and guanosine triphosphate [GTP] binding pathways) and the

Abl1 gene (intracellular tyrosine kinase).^{55–57} Although a translocation similar to *Myc* or *Notch*, the functional consequence is dissimilar in that in contrast to deregulated expression of a structurally normal gene, this chromosomal aberration results in a fusion gene with altered activity. The consequential chimeric protein underlies chronic myelogenous leukemia (CML) and encodes a constitutively active non-RTK functioning to overcome many of the requirements for cellular neoplastic change [see Figure 7]. Depending on the breakpoint in the *Bcr* gene, different variants in protein size occur, with the smaller p190^{Bcr-Abl} product associated with a more aggressive form of disease (versus p210^{Bcr-Abl}).^{29,57} Biologic actions include activation of cell cycle-promoting proteins, thus driving proliferation; impairment of the DNA repair process, with resultant enhancement of genomic instability; activation of other intracellular oncogenic proteins, such as Ras, further enhancing growth factor independence; and enhanced resistance to programmed cell death via interaction with Bcl-2.⁵⁷ This constellation of aberrant signaling is sufficient for tumorigenesis (in this case, leukemogenesis) and is in itself a cogent model for the multistep progression of malignant transformation. Also remarkable is that investigation to treat this disease prompted the advent of a novel therapeutic RTK inhibitor, imatinib mesylate, which occupies the nucleotide-binding pocket of the fusion protein, inhibiting substrate phosphorylation via blocking access to ATP.⁵⁷ This compound was initially recognized for blocking the kinase domain of PDGFR; however, it was subsequently demonstrated to inhibit both the *Abl1* kinase and *c-Kit* kinase, leading to its use in CML and GISTs.²⁹ Development of this compound provided the substratum for using specific molecular therapeutics and revealed that these targeted therapies can be efficacious. Of note, imatinib-resistant mutations

Figure 7 Translocation in chronic myelogenous leukemia. The t(9;22) chromosomal translocation produces a truncated chromosome 22 in which the *Bcr* breakpoint gene (22q11) is adjacent to the *Abl1* (9q34) gene. The resulting constitutively active chimeric protein is an intracellular tyrosine kinase functioning to promote proliferation, cell survival, and genomic instability.

have been identified in patients who relapse, which has led to the development of second- and third-generation small molecule inhibitors (dasatinib and nilotinib) of Bcr-Abl1.⁴²

Historically considered rare occurrences, given the number of cancers associated with chromosomal abnormalities, these events are no longer infrequently encountered in malignancy, and understanding the etiology and mechanism could allow directed treatment and focus on prevention. Moreover, improved diagnostic techniques, such as molecular cytogenetic analysis, have enabled elucidation of an increased number of fusion abnormalities, such as *Abl1* to *NUP214* in T cell acute lymphoblastic leukemia (transcriptional activation) and *PML* to *RARA*, *RUNX1-RUNX1T1*, or *CVFB-MYH11* (transcriptional repression inhibiting differentiation) in acute myeloid leukemia.^{29,42,58} Because the pathology underlying acute promyelocytic leukemia involves repression of transcription factors vital to normal myeloid differentiation, elucidation of the chimeric protein responsible led to successful treatment with all-*trans* retinoic acid and arsenic trioxide, which release the transcription inhibitors and/or degrade the aberrant protein, allowing differentiation to occur.⁴² Additionally, fusion aberrancies detected in virtually all cases of Ewing sarcoma include the *EWSR1* gene (potent transactivator domain) and *FLI1* (in 85%) or *ERG* (in 10%), which are genes encoding a member of the ETS family of transcription factors.^{59,60} This chimeric protein retains the DNA-binding domain of the transcription factors combined with the transactivation properties of *EWSR1* to promote tumor formation.⁴² Some fraction of prostate cancers were also recently found to harbor a chromosomal translocation that results in overexpression of a member of the ETS family of transcription factors such as the *ERG* gene or *ETV1* gene as a result of fusion with the prostate-specific, androgen-driven *TMPS2* promoter.^{29,42} Although information regarding chromosomal translocations contributing to malignant transformation continues to increase as more cancers are implicated, the causes of these rearrangement events remain unknown.

Other Mitogenic Signaling Systems

Binding of ligands to receptors other than transmembrane tyrosine kinases has been found to promote cell proliferation; among these are interleukins binding to membrane glycoproteins.⁸ For instance, interleukin-2 (IL-2) binding to its receptor activates an intracellular member of the Src family of tyrosine kinases (Lck) and results in cell growth. This is relevant in human T cell tumors that are associated with human T cell lymphotropic virus type I (HTLV-1) infection, which upregulate IL-2 as well as expression of its receptor. In normal lymphocytes, growth will occur for a restricted period in the presence of IL-2 and induction of the IL-2 receptor. Conversely, T cells infected with HTLV-I produce constitutive expression of IL-2 receptors; thus, the cells are able to grow indefinitely.⁶¹

Another recently discovered class of molecules found to be integral to both normal and tumor cell proliferation is the microRNAs (miRNAs). MicroRNAs are single RNA strands of approximately 21 to 23 nucleotides that can bind to messenger RNA (mRNA), thus blocking translation or promoting degradation of the mRNA. The RNA sequences found to be susceptible to miRNA-mediated degradation have been shown to be integral to normal development, differentiation, proliferation, and apoptosis.⁶² MicroRNAs have been implicated in various malignancies and are deregulated in a fashion similar to that of genetic lesions, including rearrangements, deletions, amplifications, or epigenetic alterations.^{6,63} The oncogenic action of miRNAs can occur when they are upregulated and bind to the mRNA, thereby inhibiting the activity of tumor suppressor genes. Alternatively, miRNAs that usually bind oncogenes can be downregulated with the same end result: an increase in growth signaling. For instance, in chronic lymphocytic leukemia (CLL), deletion at 13q14 results in decreased levels of miR-15a and miR-16-1. In this cell type, these two miRNAs function to suppress Bcl-2; thus, loss enables overexpression of Bcl-2, which protects the cell from apoptosis and provides a growth

advantage.^{62,64} In contrast, miR-21 has been found to be overexpressed in glioblastoma and cholangiocarcinoma. This miRNA appears to target and degrade the mRNA encoding *PTEN*, a tumor suppressor gene encoding a phosphatase that inhibits growth and survival pathways.^{62,65}

Interestingly, an miRNA may promote cell growth or, conversely, act to inhibit proliferation depending on the cell type and pattern of mRNA expression. Therefore, miRNAs can target multiple mRNAs contingent on the cell type and produce dichotomous effects on cell proliferation. Furthermore, a single mRNA can be targeted by many miRNAs, also conditional on cell specifications. For example, miR-15a and miR16-1 are downregulated in lymphocytes to allow for overexpression of Bcl-2, whereas they are overexpressed in pancreatic neuroendocrine tumors.^{62,66} Additionally, cellular miRNA profiles have been associated with prognosis together with response to treatment.⁶² Although understanding of miRNA involvement in cancer is relatively immature, further investigation in this area will provide better delineation of its utility in transformation to malignant disease, which may allow development of new strategies in cancer diagnosis and treatment.

INSENSITIVITY TO GROWTH INHIBITORY SIGNALS

Of the many proto-oncogenes and growth inhibitory genes that are dysfunctional in cancer, most alterations result in the activation of signaling pathways mimicking persistent exogenous stimulation. Whether ligand, receptor, intracellular protein, or downstream signaling molecule, the pathways appear to converge on the critical regulatory step of passage from G₁ into S. This is accomplished via promoting stimulators such as growth factor receptors, cyclins, and CdKs; additionally, this is achieved via overriding inhibitors and checkpoint controls, preventing cell cycle exit, and impeding programmed cell death.

Discovery of Tumor Suppressors

Oncogene gain of function and tumor suppressor loss of function are different physiologically, and both are necessary to achieve malignant status.³⁰ In normal replicating cells, proliferation mediated by proto-oncogenes is effectively counterbalanced by inhibition from tumor suppressor genes, thus carefully regulating the division of cells.³⁰ The foundation underlying tumor suppressor genes, including relevance toward cancer formation, was achieved via several distinct investigative studies. Early support from somatic cell hybridization fusing tumor cells with normal cells generated a non-tumorigenic hybrid, which led to the theory that normal cells contributed inhibitory genetic information that had been lost in the neoplastic counterparts.^{30,67} Also intriguing was the fact that with certain chromosomal loss in these hybrids, the cells would regain their tumorigenic status.^{29,67} Observations of specific chromosome losses were correlated with reversion to a malignant phenotype, which allowed for the identification of the presumptive growth suppressors. Although greatly enhancing the development of a tumorigenic model, specific genes were not elucidated at that time. However, this combination of findings led to the hypothesis that in addition to generation of growth stimulatory signals, growth inhibitory signals also exist and must be lost for cancer to occur.

Analysis of childhood malignancies associated with hereditary features also indicated the obligate loss of growth inhibitory signals for malignant transformation. The pediatric tumor retinoblastoma was used for a number of early studies in this field. Alfred Knudson studied this rare tumor and concluded that two discrete events are required to generate neoplastic change occurring in a hereditary or nonhereditary fashion (the so-called “two-hit hypothesis”).⁶⁸ His observations explained the familial form (referred to as the “dominant form”) in which an inherited germline lesion was followed by a single somatic mutation during life; the manifestations included earlier onset and bilateral disease. In addition, he determined that sporadic retinoblastoma was the result of both lesions sustained as somatic mutations (recessive form) characterized by unilateral disease later in life. Ensuing analyses of the tumor retinoblastoma revealed that the discrete events occurred on chromosome 13 and involved alteration of both copies of the retinoblastoma gene.⁶⁹ The initial insult compromising this genetic locus occurred via a germline or somatic mutation. Loss of one allele was then followed by chromosomal nondisjunction, mitotic recombination, gene conversion, or gross deletion. Given that the adjacent genetic material would also be affected by such events, DNA markers (such as restriction fragment length polymorphisms [RFLPs] or single nucleotide polymorphisms [SNPs]) of these contiguous sites would likewise reflect these changes. Therefore, specific chromosomal events generate a homozygous reduction in the chromosomal markers (and allele) where previously there had been heterozygous mapping (i.e., when only a single event was present). The LOH at these loci correlates with loss of tumor suppressor gene function.^{30,70}

Consequent studies of the pattern of DNA markers on chromosomes from numerous tumors led to the discovery of various loci containing tumor suppressor genes. As the years have progressed, these large loci have been focused, allowing characterization of specific genes. There are many known tumor suppressor genes with a vast array of cellular functions. It is now recognized that tumor suppressor genes regulate various cellular activities, such as checkpoint control, detection and repair of DNA damage, protein degradation, mitogenic signaling, cell migration, and cell differentiation [see Table 2].²³

Cell Cycle Genes and RB1 Pathway

Multiple cellular proteins interact during the early phase of the cell cycle, and the integration of these signals determines the fate of that cell. Sustained growth signals through any number of checkpoints within the cellular regulatory machinery can induce the cell to proceed inappropriately with replication. CdK4 inhibitor INK4a (CdkN2, Cdk4I, or Mts1, also known as p16^{INK4a}) is a critical regulatory protein that provides additional levels of regulation via inhibition of the cyclin D1–CdK complex. The actions of p16^{INK4a} lead to cell cycle arrest at the G₁ to S interface, just prior to the convergence point of pRB [see Cell Cycle, above]. Unfortunately, inactivation of p16^{INK4a} by any number of mechanisms leads to a constitutively phosphorylated state of pRB, providing the cell with a survival advantage. Mice nullizygous for the CdK inhibitor develop spontaneous tumors at an early age, and transformation occurs at an accelerated rate in response to carcinogens, indicating cooperation with other oncogenic

Table 2 Nonexhaustive List of Selected Tumor Suppressor Genes Associated with Inherited Susceptibility

Gene	Gene Product	Somatic Cancer Association	Germline Cancer Association
<i>PTEN</i>	Tyrosine phosphatase	Gliomas; breast, prostate, endometrial, and ovarian cancer	Prostate and endometrial cancer, melanoma, leukemia (Cowden syndrome)
<i>p16^{INK4a}</i> (CDKN2, MTS1, CDK41)	Cyclin-dependent kinase inhibitor	Biliary, esophageal, nasopharyngeal, bladder, NSCL, prostate, pancreatic, renal cell, colon, breast, ovarian cancer; gliomas; mesotheliomas; ALL; sarcoma	Familial melanoma and pancreatic cancer
<i>RB1</i>	E2F protein inhibitor	Retinoblastoma, SCLC, osteosarcoma, carcinoid, breast, prostate, and bladder cancer	Retinoblastoma
<i>p53</i>	Transcription factor	≈50% of all cancers (lung, breast, colon, esophageal, liver, bladder, ovarian, etc.)	Li-Fraumeni syndrome
<i>p14^{ARF}</i>	MDM2 antagonist	Breast and colon cancer	Familial melanoma
<i>APC</i>	Regulator of β -catenin	Colon and rectal cancer	Familial adenomatous polyposis
<i>PTCH</i>	TR involved in hedgehog signaling	Medulloblastoma, BCC, rhabdomyosarcoma	Basal cell nevus syndrome (Gorlin)
<i>Smad4</i> (DPC4)	TGF- β signaling	Pancreatic and colon cancer	Juvenile polyposis (hamartomas)
<i>TSC1/2</i>	GAP complex	Renal cell carcinoma, angiofibroma	Tuberous sclerosis (hamartomas)
<i>NF-1</i>	Ras GTPase	Sarcomas, gliomas	Neurofibromatosis
<i>WT1</i>	Transcription factor		Wilms tumor
<i>MLH1, MSH2</i>	DNA mismatch repair	Endometrial, gastric, ovarian, and bladder cancer	HNPCC (Lynch syndrome)
<i>ATM</i>	S/T PK involved in DNA break repair	Lymphoreticular malignancies	Ataxia-telangiectasia, T cell lymphoma
<i>NBS1</i>	Double-stranded break sensor complex protein	Lymphoreticular malignancies	Nijmegen breakage syndrome, T cell lymphoma
<i>CHK2</i>	S/T PK involved in DNA break repair		Li-Fraumeni syndrome
<i>BRCA1</i>	Double-stranded break repair protein	Ovarian cancer	Familial breast and ovarian cancer, pancreatic cancer
<i>BRCA2</i>	Double-stranded break repair protein		Familial breast and ovarian cancer, pancreatic cancer, melanoma
<i>TGFβRII</i>	TGF- β receptor	Colon and rectal cancer	
<i>VHL</i>	E3 ligase recognition factor for HIF α	Renal cell carcinoma, cerebellar hemangiosarcoma	von Hippel-Lindau syndrome

ALL = acute lymphoblastic leukemia; BCC = basal cell carcinoma; GAP = guanosine triphosphatase-activating protein; GTPase = guanosine triphosphatase; HIF = hypoxia-inducible factor; HNPCC = hereditary nonpolyposis colorectal cancer; NSCL = non-small cell lung; PK = protein kinase; SCLC = small cell lung cancer; S/T = serine/threonine; TGF = transforming growth factor; TR = transmembrane receptor.

mechanisms to produce tumors.⁷ In comparison, animals still possessing the *INK4a* locus were significantly more resistant, illustrating its function as a critical growth inhibitory (tumor suppressor) gene.⁷¹ Consistent with the hereditary nature in which tumor suppressor genes were discovered, germline mutations of *p16^{INK4a}* are responsible for cases of familial melanoma.⁷² Because of the significant role of *p16^{INK4a}* at a point where a delicate balance of progrowth and inhibitory signals converge, not surprising is the fact that mutations, deletions, or DNA methylation of *p16^{INK4a}* occur in a wide spectrum of malignant diseases, including pancreatic, esophageal, colon, breast, and ovarian cancer, among others [see Table 2].^{3,71}

Interestingly, both proteins from the *INK4a* locus are relevant toward inhibition of malignant transformation. A depiction of the *INK4a* locus is demonstrated in Figure 8. The *p16^{INK4a}* counterpart, *p14^{ARF}*, joins its alternatively spliced cohort as a tumor suppressor involved in many malignancies. Similar to *p16^{INK4a}*, an inherited germline mutation results in a familial form of melanoma.²³ However, whereas *p16^{INK4a}* provides regulatory activity of pRB, *p14^{ARF}* targets MDM2, a protein negatively regulating p53.^{25,27} Confirming the importance of this locus in tumor regulation, hyperproliferative signals, such as occur with constitutive activation of the *Ras* oncogene, result in transcription of both *p16^{INK4a}* and *p14^{ARF}*, promoting pRB and p53 function, respectively, thereby

Figure 8 The *INK4A* locus.⁷¹ The *INK4A* locus possesses two alternatively spliced gene sequences (each has its own promoter region) encoding proteins critical for the tumor suppressor capabilities of a cell. The first protein, p14^{ARF}, is a 14 kDa protein in which the coding region is composed of exon 1 β and a portion of exon 2 (the termination region is depicted by a *small gray arrow*). The second protein, p16^{INK4A}, arises from alternative splicing using exon 1 α , exon 2, and exon 3 (the termination region is also depicted by a *small gray arrow*). Given that these proteins are responsible for deinhibition of p53 and pRB, respectively, the *INK4A* locus is targeted in many human cancers [see Table 2].

countering the growth-promoting signals of Ras.^{23,73} However, loss-of-function mutations in the p16^{INK4A} and p14^{ARF} genes would allow for growth selection of cells with a constitutively active form of Ras. Whereas inactivating mutations specifically targeting p14^{ARF} are uncommon, lesions disrupting the *INK4a* locus and transcription repression via epigenetic modification through promoter hypermethylation are more common strategies used by cancer.⁷⁴

In continuity with the CdK inhibitors and cyclin-CdK complexes, pRB is a convergence of the intricate interplay between these proteins. In its proliferative inhibitory state (hypophosphorylated), pRB sequesters the transcription activators E2Fs, rendering them unable to promote passage from G₁ into S. The retinoblastoma gene was the first tumor suppressor identified, and study of this gene led to Knudson's two-hit hypothesis. Following Knudson's seminal work, others studying tumor viruses provided insight into the function of pRB. For example, the E1A protein encoded by human adenovirus, the large T-antigen of simian virus 40 (SV40), and the E7 protein of human papillomavirus (HPV) all complex with and inhibit pRB function.^{29,30} Subsequently, it was determined that these proteins bind to the hypophosphorylated form of pRB and not the hyperphosphorylated counterpart, indicating E2F-suppressive activity of pRB only in the hypophosphorylated state.⁷⁵ Confirmatory evidence came from observations demonstrating that hypophosphorylated, but not hyperphosphorylated, pRB was able to bind to E2F.³⁰

Thus, transformation by these viruses is achieved in part by neutralizing the growth constraints imposed by pRB. Because of its significant involvement in growth inhibition, loss of this gene is implicated in numerous malignant tumor growths [see Table 2]. Further illustration of this critical point as a common target in cancer is that alteration of any upstream component in the pRB pathway generating the common end point of pRB inactivation is generally mutually exclusive with abnormalities of other components.⁷⁶ Thus, a malignant cell need

only achieve deregulation of pRB via targeting any constituent (i.e., CdK inhibitors, cyclins, CdKs, pRB) before continuing its selection for other requisite tumor characteristics. A remarkable finding emphasizing the importance of these pathways is that in almost 100% of lung and esophageal carcinoma, there are detectable lesions in *INK4a*, cyclin D₁, or the retinoblastoma gene.³ Another intriguing function of pRB is its ability to bind the catalytic domain of the nuclear tyrosine kinase c-Abl and inhibit its function. Similar to its interaction with E2F, loss of pRB's function leads to the activation of the catalytic domain of c-Abl, thereby enabling unregulated growth-promoting signals.¹³

A concept incongruous with many tumor suppressor genes is haploinsufficiency, in which selective advantage for growth occurs with loss of only one allele. An example is p27^{Kip1}, in which animals lacking the gene develop tumors spontaneously in addition to demonstrating increased sensitivity to carcinogens. Tumor formation is dose dependent in that a lack of both copies produces faster onset tumor formation than a lack of one copy alone.⁷⁷ Despite this, reduced levels of p27^{Kip1} are not a specific genetic target for cancer; however, reduced levels are associated with a poor prognosis in a multitude of malignant disease, such as breast, prostate, and gastric carcinoma.⁷

Inherited Susceptibility

Modeled after retinoblastoma for its resemblance of familial inheritance and sporadic cases, Wilms tumor (WT) of the kidney is a result of the loss of the tumor suppressor gene *WT1*.⁷⁸ *WT1* encodes a protein that functions as a transcription factor antagonizing growth stimulation.

Familial adenomatous polyposis (FAP) is a heritable disease leading to polyposis of the large intestine with impending colon cancer if left untreated. This disease is caused by germline mutation in the adenomatous polyposis coli (*APC*) gene. Although germline mutations predispose to cancer at a young age, *APC* gene mutations are found in more than 80% of

spontaneous colon and rectal cancers.²³ In fact, mutations in *APC* have been commonly identified within benign tumors such as small adenomas and later-stage colon cancers, indicating an early event in transformation.^{79,80} Functionally, the APC protein associates with β -catenin in a scaffold complex that allows phosphorylation by glycogen synthase kinase-3 β (GSK-3 β). Phosphorylated β -catenin is targeted for degradation via an E3 ubiquitin protein ligase. In the presence of Wnt signaling, the kinase activity of GSK-3 β is inhibited, resulting in stabilization of β -catenin and association with Tcf/Lef protein complexes promoting transcription of target genes, including *C-Myc* and *CCND1*.^{23,81} Although disruption of this pathway in the mouse model (Tcf7/2^{-/-} mice) depletes intestinal epithelial stem cells, *APC* mutations in humans generate deinhibition, resulting in sustained activation and persistent propagation of growth signals.⁸² Moreover, investigations implementing a mouse model heterozygous for mutations in the *APC* gene (multiple intestinal neoplasia or Min (*APC*^{Min/+}) mouse) revealed development of numerous adenomatous polyps throughout the small and large intestine on loss of the remaining wild-type gene.^{83,84} These findings indicate that this pathway is essential for normal development, but abuse of the pathway leads to a premalignant state.⁸⁵

Also identified as mutated in colon cancer, *Smad4* was first recognized as a tumor suppressor deleted in pancreatic cancer. *Smad4* is similar to *APC* in that it is likely an early event in transformation, and germline mutations in this gene result in familial juvenile polyposis, demonstrating the importance in growth inhibition of the normal protein.⁸⁶ Its mechanistic pathway begins when TGF- β binds the TGF- β R; Smad proteins are phosphorylated, resulting in hetero-oligomeric Smad complexes that function to activate transcription of TGF- β -responsive genes involved mostly with downregulation or inhibition of growth stimulators.²³ Thus, mutations in *Smad4* disrupt the growth inhibitory input provided by TGF- β in the colon or pancreatic epithelial cells.

Another signaling cascade that is important, as evidenced by the many associated predisposition syndromes, is the mammalian target of rapamycin (mTOR) pathway. One of the upstream regulators of mTOR is Akt, which, when activated, signals enhanced protein synthesis, cell growth and progression, angiogenesis, and survival via mTOR; in contrast, a key regulator of Akt is PTEN (for phosphatase and tensin homologue). This gene encodes a phosphatase protein that inhibits growth signaling via the PI₃ kinase-Akt-mTOR pathway.^{42,87} PTEN is frequently targeted in malignant disease and loss of PTEN inhibition creates a state of constitutive activation by PI₃ kinase. Loss of this gene via somatic mutations results in survival advantage and is prevalent in multiple forms of cancer, including gliomas and prostate, endometrial, and endometrioid ovarian cancer.⁸⁸ Germline mutation with LOH and subsequent silencing of the remaining allele are found in four rare human diseases, one of which is Cowden disease, characterized by hamartomas and predisposition to breast cancer.⁸⁹ As noted, the convergence point of the PTEN/Akt in conjunction with other pathways is mTOR, underlying the motivation for targeting this protein using pharmacotherapeutics. In an attempt to restore the growth inhibitory attribute of tumor suppression, use of mTOR inhibitors (sirolimus) has shown promise in PTEN-deficient tumors.^{42,87}

Genomic Integrity

In concordance with assimilation of growth signaling, another task of tumor suppressor genes is ensuring duplication of the appropriate genetic material. The substantial size of DNA and proclivity to accumulate lesions via numerous exogenous and endogenous mechanisms result in an immeasurable task of maintaining genomic integrity such that proper cell replication and survival occur. However, when lesions are undetected or undergo faulty repair, these gene mutations can be passed on to the daughter cells through mitosis. This genome instability is a hallmark of cancer.³⁰ Because of the critical nature regarding conservation of genetic information, an intricate network of surveillance, checkpoints, and effector systems is in place to ensure propagation of conserved material. Unfortunately, these systems are prone to dysregulation in malignant disease, which provides an avenue for transformation. The initial insult may establish growth advantage, but the vulnerability that follows permits additional genetic and epigenetic changes, facilitating complete malignant degeneration.⁹⁰ Genes susceptible to loss of suppressor activity that are charged with preventing instability and promoting integrity include *p53*, *BRCA*, and the mismatch repair genes *Msh2* and *Mlh1*.

An inhibitory protein that has been studied extensively is p53, a 53 kDa nuclear phosphoprotein integral to regulating cell proliferation, maintaining the integrity of the genome, and, in dire situations, promoting cell death through apoptosis. For instance, when DNA is damaged via irradiation, drug toxicity, hypoxia, or oncogene activation, p53 halts cell cycle progression to regain DNA integrity.^{23,27} Similar to pRB, p53 was found initially from its association with an oncoprotein of SV40 (large T antigen) in transformed cells; subsequent associations were also seen with adenovirus E1B and HPV E6 proteins.^{30,91} However, unlike pRB, p53 was expressed at low levels in normal cells and found to be significantly elevated in tumor cells, leading to postulation of *p53* as an oncogene; this theory was soon dismissed as wild-type p53 was shown to be an inhibitor of tumor formation.^{92,93} The rationale for elevated levels of mutant p53 in malignant cells stems from observations that the mutant form becomes bound to heat shock proteins (Hsc70), decreasing degradation. In addition, whereas normal p53 assembles into oligomeric structures prior to DNA binding, mutant forms from point mutations, deletions, or rearrangements also complex with normal p53 and block the DNA-binding function in a dominant negative fashion.⁹⁴ Thus, in its mutated state, p53 accumulates within the cell (half-life extends from 20 minutes to 24 hours), is unable to bind DNA due to misfolding, and therefore is unable to perform its normal effector functions. With loss of regulation, the resulting genetic instability leads to disturbance of the intact genome and ensuing disruption of chromosome integrity, which generates an environment conducive to malignant transformation.^{30,92} Successive aberrancies accumulate, which may provide favorable attributes such as avoidance of programmed cell death, promotion of angiogenesis, enhanced aggression, and invasiveness, ultimately producing a highly malignant, chemoresistant tumor.³

Further similarities to pRB constitute inherited disorders secondary to germline mutations, namely, Li-Fraumeni syndrome. Affirming p53 as a critical protein regarding tumor

suppression, patients with Li-Fraumeni syndrome develop tumors in a variety of organ systems, including the colon, breast, lung, larynx, and brain, as well as increased incidence of rhabdomyosarcoma, adrenocortical carcinoma, melanoma, and leukemia.³⁰ Similarly, sporadic loss of this crucial gene has also been detected in a multitude of cancers [see Table 2]. Additionally, although the normal protein has been shown to demonstrate antineoplastic properties in both in vitro and animal models, transgenic mice lacking p53 are prone to tumor development, substantiating the pivotal nature of p53 mutation in cancer formation.⁹⁵ With the understanding of its many regulatory functions, it is not surprising that p53 is the most frequently mutated gene in human cancer.^{96,97} In addition, given the many distinct codons in which potential debilitating alterations may occur, this gene then becomes quite susceptible and a propitious target to overcome antineoplastic defenses of the cell.⁹⁵

BRCA1 and BRCA2 are proteins involved in the repair of double-stranded DNA breaks by homologous recombination. Mutations in either of these genes confer a risk of developing breast cancer 10 to 30 times that of the general population, with manifestations of earlier onset and bilateral disease. Important for treatment options, breast cancers related to BRCA1 mutations are often high-grade, aneuploid malignancies that do not express estrogen receptor, progesterone receptor, or HER2 (triple negative).⁹⁸ Thus, alternative chemotherapeutic avenues have been investigated. Tumors deficient in one of these proteins were found to be potentially treatable by inhibitors of the single-stranded break repair protein poly ADP-ribose polymerase (PARP).⁹⁹ PARP proteins are enzymes that play an integral role in the repair of single-stranded DNA breaks. Thus, use of an inhibitor, olaparib, may lead to an accumulation of single-stranded breaks that consequently form double-stranded DNA breaks.¹⁰⁰ In normal cells, repair of the damaged genetic material would ensue, using the homologous recombination double-stranded DNA repair pathway (i.e., BRCA1 or BRCA2). However, cells that have lost BRCA functions are particularly susceptible to double-stranded breaks as no backup repair system exists.¹⁰⁰ The premise of cytotoxicity only to cancer cells was based on the idea that wild-type BRCA and PARP were sufficient to prevent cell death, whereas loss of BRCA itself promoted genomic instability and malignant transformation, but that loss of both BRCA and PARP generated an environment not conducive to survival. Phase I trials with olaparib have demonstrated antitumor activity in breast, ovarian, and prostate cancer.¹⁰⁰

Mutations in mismatch repair (*MMR*) genes have been discovered to play a role in hereditary nonpolyposis colorectal cancer (HNPCC). DNA replication errors, including single base mispairing and erroneous reproduction of microsatellite sequences (such as slipped strand mispairing), are frequently corrected by this class of DNA repair genes.² Microsatellites are tandem repeats of di-, tri-, or tetranucleotide sequences, and these microsatellite loci associate with alleles and serve as markers for loss of the mismatch repair gene functions.²⁹ The repair system encompasses the *MutS* genes (*Msh2*, *Msh3*, *Msh6*), which recognize DNA mismatch via assembly of *Msh2* with either *Msh6* or *Msh3*, and *MutL* genes (*Mlh1*, *Mlh3*, *Pms1*, *Pms2*), which function to correct the defect accomplished via excision by the *Mlh1*/*Pms1* complex.²³ HNPCC

comprises 1 to 3% of colon and rectal cancer, with approximately 95% of HNPCC derived from mutations in *Mlh1* and *Msh2*.² In addition to colon and rectal cancer, patients with this syndrome are also at risk for cancers of the ovary, endometrium, bladder, small intestine, and pancreas.¹⁰¹ Consistent with the characteristics of other inherited disorders, sporadic biallelic lesions also occur and are present in 15% of colon and rectal tumors, mostly arising from inactivation of *Mlh1*, which results in microsatellite instability. Whether sporadic or germline in nature, alteration of the repair system generates an unstable environment in which mutations in other genes occur. In this intriguing novel pathway of tumorigenesis, one can envision that targets of the so-called “mutator” phenotype could lead to activation of oncogenes as well as inactivation of tumor suppressor genes.²³ Indeed, microsatellites are present within the coding sequence of growth inhibitory genes such as transforming growth factor- β receptor II (*TGF- β R*), growth-promoting genes such as insulinlike growth factor II receptor (*IGF2R*) and *E2Fs*, apoptosis regulators including *Bax*, and mismatch repair genes themselves.² Given that mutations in the *MMR* genes confer significant risk of developing colon and rectal cancer, patients designated with inherited susceptibility must undergo lifelong surveillance to identify development of invasive disease.

Other response-and-repair mechanisms are also in place within the cell, each activated via specific mechanisms and functioning to maintain DNA integrity. One example is the ataxia-telangiectasia gene (*ATM*), which encodes a kinase that senses double-stranded DNA breaks occurring from ionizing radiation. Once activated, *ATM* phosphorylates a variety of proteins, such as p53, checkpoint kinase 2 (*CHK2*), nijmegen breakage syndrome 1 (*NBS1*), and BRCA1, which halts cell cycle progression and enlists DNA repair processes.²³ Patients with ataxia-telangiectasia have a germline mutation of the *ATM* gene and have a syndrome characterized by neuronal degeneration, immunodeficiency, genomic instability, and cancer predisposition. Somatic mutations of the *ATM* gene have been found in various T and B cell malignancies.¹⁰² It is clear that the DNA repair genes play a significant role in protecting cells from malignant change.

Although familial cancer susceptibility is a relatively infrequent cause of malignancy, there are implications in those families afflicted by this predisposition. Genetic testing for highly penetrant genes is available, and guidelines for which individuals should undergo testing have also been standardized.⁹⁸ Unfortunately, interpretation and clinical decisions have not been simplified. With certain tumor suppressor genetic lesions, there are defined therapeutic options, such as surveillance with eventual total proctocolectomy and ileal-pouch reconstruction in patients with FAP or prophylactic bilateral mastectomy in patients carrying BRCA1 or BRCA2 mutations. However, this is not the case for the majority of patients with an inherited predisposition to cancer. As we further our understanding of heritable cancer syndromes, treatment of the genetic defects giving rise to the susceptibility will evolve.

EVADING APOPTOSIS

Corresponding with the processes of growth signaling and inhibition, apoptosis (programmed cell death) is a normal physiologic process crucial for the development and proper function of each organ system. A hallmark of cancer is

the ability of the malignant cells to resist the induction of apoptosis. In fact, many biologic systems have evolved mechanisms by which to inhibit apoptosis. For example, many viruses have implemented methods in which to control programmed cell death. The adenovirus protein E1B55 disrupts p53 function to abate upstream apoptosis signaling; furthermore, proteins E1B19 and E3-14.7, which are a Bcl-2 homologue and a caspase-8 inhibitor, respectively, function to inhibit apoptosis at downstream junctures.¹⁰³ This ability to circumvent programmed cell death provided a distinct growth advantage for the infected cells, prolonging the duration of survival. Investigation of these strategies used by viruses has once again resulted in the identification of the mechanisms by which viruses usurp the apoptotic pathways of cells. These discoveries have been directly related to malignant cells, providing insight into the pathways that are commonly disrupted, resulting in escape from programmed cell death.

When a proapoptotic signal is received by the normal cell, cysteine proteases called caspases orchestrate events, resulting in subsequent morphologic changes such as cell shrinkage, membrane blebbing, and reduction into apoptotic bodies.¹⁰⁴ During this process, certain phospholipids (phosphatidylserine) become exposed externally, thereby triggering clearance via macrophages.¹⁰⁵ Two distinct signaling pathways are responsible for the induction of apoptosis in eukaryotic cells. The intrinsic pathway is p53 dependent and responsive to various intracellular stimuli such as DNA damage, growth factor withdrawal, corticosteroids, oncogene activation, hypoxia, or other stress-induced signals.¹⁰⁶ This pathway is ultimately regulated by the Bcl-2 family of proteins, which contains a member that inhibits apoptosis, Bcl-2, and members that stimulate apoptosis, Bax and Bak.^{107,108} When activated, Bax and Bak heterodimerize and promote pore formation in the outer mitochondrial membrane, with resultant release of cytochrome *c*. A complex then forms, including cytochrome *c*, Apaf-1 (adaptor protein), and procaspase-9 (the so-called apoptosome), which then activates caspase-9 and the subsequent executioner caspases [see Figure 9].¹⁰⁷ Inhibition of apoptosis induced by the activation of the apoptosome is a target of Ras and PI₃ kinase, which contribute to the phosphorylation and inactivation of caspase-9.¹⁰⁹

The extrinsic apoptotic pathway in eukaryotic cells is dependent on the activation of any number of cell death receptors binding to their respective ligands. Included among these are Fas and TNF, which bind the DR4 and DR5 receptors. Activation of these receptors by their respective ligands initiates the caspase pathway mediated by the Fas-associated protein with death domain (FADD) protein.¹¹⁰ For instance, when the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) binds to either DR4 or DR5, trimerization occurs, with conformational change in the intracellular death domain.¹⁰⁶ This conformational change in the intracellular death domain results in the binding of FADD as well as procaspase-8 or -10, inducing autoactivation. Activation of caspase-8 or -10 by this death-induced signaling complex (DISC) propagates its signal through the executioner caspases.¹¹⁰ The intrinsic and extrinsic pathways crosstalk at the induction of Bid into active tBid, stimulating Bax-mediated permeabilization of the mitochondrial membrane and release of cytochrome *c* [see Figure 9].¹¹¹

The executioner caspases include 3, 6, and 7, and they function to cleave and inactivate other cellular proteins vital for cell survival, such as DNA repair enzymes, protein kinases, MDM2, lamin, and gelsolin.¹¹² In addition, the caspase-activated DNase (CAD) is bound to its inhibitor, iCAD, rendering it inactive until apoptosis is triggered. DNA cleavage is induced when iCAD is cleaved by caspases releasing CAD.¹⁰³

Many normal processes use the apoptotic pathways to regulate cell number. For example, contact inhibition from adjacent cells can quickly trigger apoptosis, eliminating excess cells and preventing overgrowth of normal tissues.¹⁰³ Various oncogenes have also been shown to induce the programmed death cascade. Loss of the ability to induce apoptosis provides transformed cells with a growth advantage and results in uncontrolled proliferation.¹⁰³ Loss of p53 function provides transformed cells with this growth advantage.¹¹³ Gain-of-function mutations can also result in a growth advantage via inhibition of apoptosis. Specifically, overexpression of Bcl-2 protects cells from programmed cell death mediated by the intrinsic pathway. Transgenic mice overexpressing Bcl-2 have been shown to be more prone to developing lymphoid tumors than wild-type mice.¹¹⁴ Additionally, the importance of programmed cell death was demonstrated when lymphoid cells from mice with myc deregulation were found to be hyperproliferative, with a concomitant increase in apoptosis. When Bcl-2 was upregulated, inhibiting apoptosis in these cells, hematogenous malignancy developed at a relatively rapid rate.^{114,115} These findings were corroborated by investigations of human follicular B cell lymphomas in which the underlying pathogenesis involved Bcl-2 upregulation. Chromosomal translocation results in Bcl-2 overexpression mediated by the transcriptional enhancer of the immunoglobulin heavy chain (IgH).¹¹⁴

Bcl-2 is a master regulator of apoptosis. Its expression is controlled in a negative feedback loop involving the Bax protein. This member of the Bcl-2 family induces apoptosis by blocking Bcl-2's antiapoptotic effects. Bax^{-/-} mice have been found to have decreased levels of apoptosis and be susceptible to malignant brain tumors in response to inactivation of pRb by tissue-specific SV40 T-antigen activation when compared with wild-type mice.¹¹⁶ Other cellular proteins that interact with core members of the apoptotic pathways include the inhibitor of apoptosis proteins (IAPs). Increased expression of IAPs has been demonstrated to promote tumor resistance in a number of cancer cell lines.¹⁰⁶ Finally, cells can become resistant to the extrinsic apoptosis pathway by loss of death receptor expression. For example, some colon cancers have been shown to lack Fas receptor expression and have presumably gained a selective advantage through the evasion of immune-mediated destruction via cytotoxic lymphocytes.^{107,117} As another hallmark of cancer, resistance to apoptosis is clearly a complex process, and multiple mechanisms have been discovered that allow cells to circumvent this programmed cell death.

In addition to providing a selective growth advantage to transformed cells, resistance to apoptosis can contribute to resistance to treatment. For example, many chemotherapeutics rely on inducing apoptosis, and resistance to apoptosis, as occurs by upregulation of Bcl-2, has been found in a number of cancers and correlates with chemoresistance.^{103,118} Moreover, in various experimental models, loss of Bax or

Figure 9 Apoptotic pathway. There are two generally recognized apoptotic pathways in humans. The intrinsic pathway is activated in response to DNA damage, growth factor withdrawal, oncogene activation, hypoxia, or stress; p53 promotes transcription of various proapoptotic genes, such as Bax, Bak, death receptors (DR4, DR5), Puma, and Noxa. These proapoptotic molecules, such as Bax and Bak, then oligomerize to promote outer mitochondrial membrane permeabilization and subsequent release of cytochrome *c*. Once in the cytosol, cytochrome *c* binds Apaf-1, which induces a conformational change and ensuing binding of seven Apaf-1 proteins with seven caspase-9 proteins. The complex formed is called the apoptosome and functions to activate effector caspases (caspase-3, -6, -7). These executioner caspases cleave and inactivate proteins essential for a normal functioning cell such as DNA repair enzymes, protein kinases, MDM2, gelsolin, and lamin. Additionally, the caspase-activated DNase (CAD) is released from its inhibitor (iCAD) and allowed to promote DNA cleavage. The extrinsic pathway occurs when ligands such as TRAIL or Fas bind the death receptors (DR4/5). On binding, receptor trimerization occurs, which then allows binding of FADD and caspase-8 and -10. The activated caspase-8 and -10 subsequently activate the executioner caspases (caspase-3, -6, -7) with similar downstream effects, ultimately resulting in apoptosis. Furthermore, caspase-8 and -10 can activate Bid to its functional form, tBid, which promotes Bax/Bak permeabilization of the outer mitochondrial membrane, demonstrating a crosspoint between the two pathways. Contrasting the proapoptotic molecules are proteins whose capacity include inhibition of these pathways, thus promoting cell survival. Bcl-2 is an important mediator and often exploited by malignant tumors to generate survival advantage. In addition, inhibitors of apoptosis (IAPs) are upregulated by nuclear factor- κ B (NF- κ B) in the presence of growth factors and function to inhibit caspase-3, -7, and -9. FLICE is limited to the ligand-induced pathway and blocks transmission of this signal via inhibiting the caspase-8 binding site on FADD. Apaf-1 = apoptotic protease-activating factor 1; Bak = Bcl-2 antagonist/killer; Bax = Bcl-2-associated x protein; Bid = BH3 interacting domain death agonist; FADD = Fas-associated protein with death domain; FLICE = FADD-like interleukin-1 β -converting enzyme; PUMA = p53 upregulated modulator of apoptosis; TRAIL = tumor necrosis factor-related apoptosis-inducing ligand.

overexpression of Bcl-2 has been shown to contribute to resistance to specific chemotherapeutics.^{118,119} However, not all changes in the apoptotic signaling pathway contribute to chemoresistance. For instance, caspase-8-deficient mice were found to be sensitive to apoptosis induction mediated by chemotherapeutics as well as gamma-irradiation; however,

caspase-9-deficient mice were quite resistant.^{103,120,121} In contrast to demonstrating resistance, investigations of human rectal carcinoma have revealed that tumors exhibiting higher rates of apoptosis have better local control, are associated with tumor regression when given preoperative chemoradiation, and portend a better prognosis.^{107,122} Whether conferring

tumor survival advantage or indicating response to chemotherapeutics and/or radiation, apoptosis is an essential element of tumor pathology, and most, if not all, tumors have acquired antiapoptotic modifications.

Advances in the understanding of apoptosis have resulted in new therapies targeting members of this pathway. For example, the taxane family of chemotherapeutics induces phosphorylation and inactivation of Bcl-2, and proteasome inhibitors target nuclear factor- κ B (NF- κ B), blocking the release of antiapoptotic proteins.¹⁰⁹ Rituximab, a monoclonal antibody directed against CD20, promotes cell death in B lymphocytes and provides a survival advantage to patients with B cell CLL when combined with the conventional chemotherapeutic regimen.¹²³ Rituximab has been shown to induce cell death via complement-mediated cell lysis, antibody-dependent cellular cytotoxicity (ADCC), and induction of apoptosis in cells specifically expressing CD20.¹²⁴ Other pharmaceuticals more specifically targeting apoptosis have also been developed. For instance, preclinical studies with the small molecule inhibitor of antiapoptotic proteins ABT-737 have found lymphoma and small cell lung carcinoma cells to be more sensitive to chemotherapeutics and ionizing radiation.¹²⁵ Although these preliminary in vitro studies are promising, proapoptotic drugs have also moved beyond the preclinical phase. In fact, recombinant TRAIL or antibodies designed to bind the TRAIL receptors DR4 and DR5 are under investigation in at least seven clinical trials.^{106,126} These agents, such as lexatumumab and mapatumumab (Human Genome Sciences), appear to preferentially induce apoptosis in cancer cells while producing minimal toxicity to normal cells.¹⁰⁶ Further evolution in understanding resistance to apoptosis will lead to advancement of novel therapies. Moreover, as we begin to elucidate the mechanisms of apoptosis resistance, accompanying this will be clear discernment of the role of programmed cell death in progression to the malignant phenotype.

ANGIOGENESIS

Blood vessels arise via two mechanisms, vasculogenesis and angiogenesis. Vasculogenesis is defined by a primitive vascular network created during embryonic development from multipotent mesenchymal progenitors, whereas angiogenesis encompasses the process of capillary sprouting from preexisting vessels to produce new vessels.^{127,128} When encouraged via increased proangiogenic factors and/or decreased antiangiogenic factors, proliferating endothelial cells disrupt the underlying basement membrane and migrate into surrounding stroma toward angiogenic stimuli, thus constructing new vessels.⁵¹ The process is completed with stabilization and maturation of the nascent vessels. An event essential for development and occurring in the adult during reproductive cycles or wound healing, this process is also exploited by solid tumors to sustain rapid growth.¹²⁸

Consistent with Folkman and colleagues' postulation years ago of diffusion-limited tumor growth, an expanding tumor is restrained by nutrient and oxygen supply; thus, overproliferation will be balanced with cell death, prohibiting the size attained by the tumor.^{129–131} That this restriction occurs was validated from studies in which tumor fragments were placed in the avascular cornea of rabbits, and subsequent prevention of capillary ingrowth effectively confined tumor size.^{128,129} Although tumors may acquire characteristics of hypoxic

growth, in general, cell function and survival require residence within 100 μ m of a capillary blood vessel.²⁸ Thus, tumors stimulate angiogenesis. The acquisition of neovascularization, or new vessel formation, occurs in a discrete step termed angiogenic switch, in which the previously quiescent vessels undergo angiogenesis, providing the necessary nutrient and oxygen supply and ensuing rapid expansion.¹²⁸

The ability of tumors to induce angiogenesis and the mechanism by which they accomplish this task remain active areas of investigation. Endothelial cells are among the most stable in the body, with only one in 10,000 involved in cell division at any given time (compared with one in seven for intestinal epithelial cells).¹²⁸ Therefore, the tumor-induced angiogenesis provides an interesting model for the study of vascular biology.

VEGF comprises a larger family of growth factors, designated A, B, C, D, and placental growth factor (PlGF). VEGF-A is recognized as the major member involved in tumor angiogenesis and is generally referred to as VEGF.¹³² VEGF binds to VEGF receptor 2 (VEGFR2/KDR/FLK1), which is upregulated in endothelial cells, participating in new blood vessel formation.⁴⁹ Additionally, basic fibroblast growth factor (bFGF or FGF-2) and its counterpart, acidic FGF (aFGF or FGF-1), are also involved in this process. During tumor progression, local hypoxia is induced as a tumor outgrows its blood supply. This relative hypoxic state is a potent inducer of hypoxia-inducible factors 1 α and 2 α (HIF-1 α , HIF-2 α), which are responsible for the upregulation of VEGF.¹³³ Whereas the normal von Hippel-Lindau (VHL) protein contributes to the degradation of the HIF proteins, mutations in the *VHL* gene result in constitutive activation of the HIFs, thereby promoting angiogenesis, red cell production, and glycolysis via the growth factors that are produced (VEGF, PDGF, TGF- α). Tumors that have been shown to have mutations in the *VHL* gene are highly vascular and include renal clear cell carcinomas, cerebellar hemangioblastomas, pheochromocytomas, and retinal angiomas.²³ In fact, the *VHL* gene is inactivated via deletion, mutation, or promoter methylation in up to 80% of sporadic clear cell carcinomas of the kidney.³⁹

Pathways other than VEGF have been shown to contribute to vascular cell proliferation. For example, the angiopoietin-1 tyrosine protein kinase receptor (Tie-2/TEK) is expressed predominantly in vascular endothelium and promotes endothelial proliferation when bound by angiopoietin 1 (Angpt1) or angiopoietin 2 (Angpt2). Interestingly, Angpt1 is a Tie-2 agonist and Angpt2 is a Tie-2 antagonist, but both cooperate with VEGF to promote vessel maturation and integrity.¹²⁷ In addition to their differences in function, the angiopoietin molecules also appear to be expressed at different times in development. Both appear to be integral for the in utero development of blood vessels, but only Angpt2 expression is substantially increased at sites undergoing vascular remodeling in postnatal time points.¹³⁴ Given the importance in vascular remodeling, the effect of Angpt2 antibodies on tumor vessel formation in experimental systems has been investigated. Experiments in xenograft models of epidermoid and colorectal cancer revealed a reduction in endothelial cell and tumor cell proliferation.¹³⁴ Additionally, a complete response was observed in a subset of treated mice, demonstrating the importance of this pathway in some fraction of tumors.¹³⁴ In

fact, other angiogenic factors, such as VEGF, PlGF, FGF-2, and Angpt2, have been shown to be upregulated in a number of cancers, demonstrating the importance of this hallmark of cancer on tumor potentiation.¹³⁴

A common theme in biology is the presence of a negative regulator for every positive regulator. To that end, inhibitors of angiogenesis have also been found. These include proteins induced by stimulators to regulate the angiogenic process, such as vasohibin, angiostatin, endostatin, thrombospondin-1, and tumstatin.^{49,128} Although use of two of these inhibitors, angiostatin and endostatin, demonstrated antitumor effects in mouse studies, these findings were not replicated in human trials.²⁹ Phase I clinical trials demonstrating the safety of the angiogenesis inhibitor thrombospondin-1 have been conducted.¹³⁵ This particular inhibitor is activated by p53 and contributes to angiogenesis inhibition by blocking the function of VEGF and FGF-2; it also induces apoptosis in endothelial cells.¹³⁵ Unfortunately, phase II trials in soft tissue sarcoma, renal cell carcinoma, and metastatic melanoma have not shown antitumor activity.^{136–138}

The Notch transmembrane protein also contributes to neovascularization. The Notch receptors are present on many different cell types and interact with various transmembrane ligands on neighboring cells, influencing the fate of the adjacent cell. Of the five known ligands, Notch-delta-like ligand 4 (Dll4), the expression of which is restricted to endothelial cells, was found to be essential for embryonic vascular development and arteriogenesis.^{49,139,140} Additionally, although intrinsic expression in mature vasculature is low, Dll4 is upregulated in the vasculature of various solid tumors and is increased on cells in response to VEGF-A stimulation.^{50,51,139} VEGF induction of Dll4 appears to provide a negative feedback loop in which VEGF-induced blood vessel sprouting is inhibited, whereas the growth of healthy vessels is encouraged.⁵⁰ Interestingly, although the Dll4-Notch pathway appears to suppress branching and promote vessel maturation, mice with reduced expression of Dll4 demonstrate increased density of haphazardly formed vessels, resulting in poor function.^{51,139} Similarly, in xenograft tumor models, antibodies to Dll4 increased angiogenic activity, but the neovasculature was erratic and dysfunctional, such that tumor growth was inhibited. This effect was also seen when treating tumors resistant to anti-VEGF therapy, whereas in susceptible tumors, the combination of both anti-Dll4 and anti-VEGF had a synergistic, enhanced inhibition of tumor growth.^{49,51,139,140} Furthermore, the effect was limited to the vascular compartment in areas of active vessel formation, sparing the mature vessels.¹⁴⁰ Because of these findings, selective inhibition of Dll4 may prove to be an advantageous target for cancer therapeutics.

It is apparent that tumor cells use a number of strategies to promote blood vessel formation. Initially, tumor growth may be stalled by angiogenic inhibitors. However, acquisition of the ability to promote blood vessel ingrowth may overcome this restriction. Thus, attainment of this hallmark quality allows the tumor to proliferate to a substantial size with disregard for surrounding environment.²⁸ Whether this attribute is acquired early in the course of transformation or later has not been resolved. However, studies appear to favor angiogenesis as an early- to midstage occurrence.²⁸ Investigation of separate transgenic murine models involved in multistep

tumorigenesis has revealed that angiogenesis occurred in midstage lesions prior to rapid clonal expansion or tumor formation.¹²⁸ Conclusions from these studies, in conjunction with other *in vitro* and *in vivo* findings, reveal that the ability to induce blood vessel formation appears to be required for cancer evolution and progression.

Current therapy is directed at inhibiting the interaction of VEGF-A with VEGFR2. Bevacizumab is a humanized monoclonal antibody directed against VEGF, which has been used in combination with conventional chemotherapy for the treatment of metastatic colon and rectal cancer.¹⁴¹ Antiangiogenic therapy has been shown to contribute to a survival advantage in patients with advanced colon and rectal cancer as well as an increase in overall survival in patients with non-small cell lung cancer.¹⁴² Additionally, two small molecule RTK inhibitors, sorafenib and sunitinib, that target the intracellular domain of VEGF R1 and R2 (among other RTKs) were found to improve survival in patients with metastatic renal cell carcinoma in addition to hepatocellular carcinoma.⁴⁹

Although antiangiogenic therapy conceptually has appeared quite promising, the redundancy in the proangiogenic process has proven to be a significant roadblock for the development of new drugs inhibiting tumor angiogenesis. For example, increased expression of a number of receptors, such as bFGF, PlGF, or VEGF, can promote angiogenesis by different mechanisms. Additionally, malignant cells may develop insensitivity to hypoxia via subsequent mutations in p53 or acquire the ability to rapidly form mature vessels in which drugs targeting immature vessels would become ineffective.⁴⁹ A deeper understanding of the elaborate process of angiogenesis is required to develop novel therapeutics capable of inhibiting tumor growth.

LIMITLESS REPLICATIVE POTENTIAL

In the normal state, proliferating cells undergo a defined number of cycles prior to arrest. Evidence favoring this arose from observations that human diploid fibroblasts were unable to immortalize spontaneously and underwent a characteristic number of population doublings.¹⁴³ On infection with the SV40, the cells were driven past their resting condition but only for another discrete number of cycles.¹⁴³ This stimulus eventually resulted in cell crisis, characterized by a balance between cell growth and death. The resultant genomic instability and ensuing rearrangements and chromosomal translocation events resulted in an immortalized state with some frequency (one in 10⁷ cells).^{28,144} The telomerase gene was found to be activated in these immortalized cells, and its activity was absent in cells that underwent arrest or death.¹⁴⁵

Telomerase is responsible for maintaining the integrity of the chromosomal telomere. Telomeres consist of long, repetitive hexameric nucleotide sequences located at the end of chromosomes and are accompanied by a protein complex, termed shelterin, which functions to protect the chromosome from end fusion, misrecognition as a single- or double-stranded breakpoint, and degradation.¹⁴⁴ With each cell division, these repeated sequences shorten secondary to inability to end-replicate. With continued shortening, a critical length is encountered, triggering the DNA damage repair system, and results in replication arrest as the cell is driven to senescence.¹⁴⁴ When premalignant cells replicate, telomeric repeats

at the ends of chromosomes are sequentially shortened until clonal outgrowth results in critically short telomeres signaling the DNA damage repair system to provoke cell cycle arrest and subsequent cell demise.⁹⁹ This drive toward senescence is an effective mechanism to curtail neoplastic growth, and it is therefore understandable why approximately 90% of cancers harbor reactivated telomerase.^{146,147}

Telomerase is a ribonucleoprotein complex composed of a reverse transcriptase protein subunit (hTERT) that uses its RNA template subunit (hTR) to synthesize and elongate telomeric DNA substrates, thus maintaining telomeres despite successive cell cycling.^{146,148} Its relevance in malignancy is suggested from studies evaluating immortalized cell lines that showed upregulation of telomerase activity in nearly all cell lines, whereas investigations of mortal cell lines revealed the absence of telomerase expression.¹⁴⁹ Additionally, biopsies of a variety of tumors revealed the presence of telomerase in the majority of specimens (90%) versus normal somatic tissues, which lacked evidence of the enzyme (except reproductive tissue).¹⁴⁹ Therefore, it appears that acquisition of telomerase activity is another key component in the multistep tumor process.^{143,150,151}

Drugs inhibiting the function of telomerase in cancers have been developed. Potential approaches include gene therapy, immunotherapy, or small molecule inhibitors.¹⁴⁴ One approach currently in phase I clinical trials delivers an enzyme prodrug, which forms a toxin on activation by an adenoviral vector.¹⁴⁴ The transcription of this complex is driven by the hTR promoter, which is frequently overexpressed in various cancers (e.g., ovarian, colon, pancreatic, gastric).¹⁴⁴ Oncolytic gene therapy involving adenoviruses engineered to selectively replicate within cancer cells expressing telomerase by targeting the hTERT promoter has also been investigated in phase I clinical trials.¹⁵² In preclinical studies, the telomerase-specific oncolytic adenovirus OBP-301, or telomelysin, proved efficacious both in vitro in multiple tumor cell types and in vivo using mice xenograft models with various tumors.¹⁵² A primary concern with any of these approaches centers around the presence of hTERT within normal tissues, including embryonic cells, bone marrow stem cells, and colonic crypt epithelial cells. However, these levels have been found to be significantly lower than in the malignant tissue, and no significant adverse effects have been observed thus far.¹⁴⁷

Although gene therapy manipulates tumor genetic material to achieve its response, immunotherapy directs the immune system to confront the neoplastic disease. The presence of telomerase in tumors has been exploited by immunobiologists revealing telomerase to antigen-presenting cells. Once sensitized to telomerase, cytotoxic T cells would become activated, killing any tumor cells expressing the enzyme.¹⁵³ Phase I/II clinical studies have been conducted in patients with metastatic prostate cancer and revealed a safe profile and encouraging initial results.^{144,153} Additionally, another phase I/II study using a slightly modified peptide from telomerase inducing T cell immunity toward the protein was performed on pancreatic cancer patients and is currently under evaluation in two large phase III trials.¹⁴⁷

Small molecule inhibitors are yet another category of anti-telomerase strategies developed. These small molecules cross the plasma membrane, binding to and inhibiting the function of telomerase. With proven inhibitory effects in vitro and, similarly, in vivo with xenograft models, GRN163L has

entered into early-phase trials in refractory or relapsed CLL to determine the safety profile and maximum tolerable dose.^{146,154,155} In addition, GRN163L is under investigation for combination therapy with paclitaxel and carboplatin in advanced-stage non-small cell lung cancer.¹⁴⁴

TISSUE INVASION AND METASTASIS

If discovered early enough, surgical excision of a malignant tumor is frequently curative. However, as tumors progress, the compounding nature of traits and heterogeneous populations of cells will eventually give rise to invasion. Although the nature of the invasive tendency is noteworthy, more remarkable is the fact that malignant cells can disseminate throughout the body, implant at various locations, sustain proliferation at these locations by recruiting assistance from neighboring cells, and potentiate the tumor. Although this is but one of the many attributes of cancer cells, it is irrefutably the most devastating as metastases are responsible for approximately 90% of cancer deaths.²⁸ Unfortunately, the complexities of metastases preclude an adequate understanding of the precise mechanism.

The foundation for obtaining a more encompassing depiction of metastatic pathophysiology has been generated, but this must be built on to fully comprehend the genetic alterations involved. A common consistency incorporates genomic instability of the primary tumor, providing an environment conducive for invasion. Reinforcing this mechanism includes observations that metastatic lesions at the genetic level tend to harbor an increased number of mutations and chromosomal abnormalities when compared with the primary lesion.^{156,157} Thus, the cells that metastasize are selected for their ability to invade and develop in a separate organ system. Similar to the multitude of steps required to generate the malignant primary cohort of cells, several discrete steps are necessary for invasion and metastasis. These include loss of cellular adhesion, promotion of motility, ability to penetrate barrier tissues, survival within the circulation, and extravasation with proliferation at a distant site.¹⁵⁷

Initially, metastatic cells must overcome the restraints of the tumor microenvironment. In particular, tumor cells lose contact with neighboring cells and extracellular matrix by overcoming the contact with cellular adhesion molecules (CAMs) and integrins.²⁸ This transition is accomplished via turning off expression of certain adhesion molecules while upregulating expression of others.¹⁵⁸ One such molecule that has received much attention is E-cadherin. E-cadherin maintains the tight interconnections between cells via interacting with α -, β -, and γ -catenin linking the adhesion molecule to the actin cytoskeleton.¹⁵⁸ In addition to maintaining tight junctions, E-cadherin is responsible for the transmission of antigrowth and other critical cell-cell signals.²⁸ Notably, E-cadherin's ability to mediate adhesion is lost in most human epithelial cancers via deletions, inactivation, protease-induced degradation of extracellular domain, epigenetic silencing (hypermethylation), transcriptional repression, and alterations in associated proteins.²⁸ The importance of cell adhesion has been demonstrated in vitro by the expression of E-cadherin reverting malignant cells to a more benign appearance. Furthermore, studies using transgenic mice have shown loss of E-cadherin as tumors transition from adenoma to invasive carcinoma.¹⁵⁸ From this, one can surmise that by altering cell-cell interactions, a tumor may become liberated

from adjacent inhibitions and seek to progress beyond local expansion into a more invasive phenotype.

Integrins are important mediators of a malignant cell's invasive and metastatic capability. These proteins facilitate an oncogenic phenotype and promote release from the local environment and subsequent incorporation into foreign matrix components that allow successful inhabitation of these distant sites. For instance, $\alpha_6\beta_4$ integrin interacts with oncogenic growth signaling receptors such as EGFR and HER2, whereas $\alpha_3\beta_1$ expression on tumor cells within the circulation were demonstrated to target laminin-5 in the vascular basement membrane of pulmonary metastases.¹⁵⁷ Another integrin, $\alpha_5\beta_3$, also appears to have a predilection toward adhesion of circulating tumor cells to vasculature.¹⁵⁷ The result of this dynamic interchange between a stable, locally restrictive group of adhesive molecules shifting toward an array of integrins promoting invasion and distant colonization is generation of a tumor adapted for metastasis.

In conjunction with alterations in cell-to-matrix binding is the use of matrix proteases by the malignant cell to disrupt the dense network of the basement membrane underlying epithelial and endothelial cell layers. Normally, a physical boundary with vast signaling capabilities and carefully regimented matrix protease activity, the basement membrane and extracellular matrix can be disturbed via release of various mediators such as matrix metalloproteinases (MMPs) from cancerous cells. For example, MMP-2 and MMP-9 have been implicated in cancer cell invasion, whereas MMP-1 appears to be critical for breast cancer spread to the lungs and bone.¹⁵⁹ This upregulation can either occur from the cancer cell itself or from induction of the supporting stroma and inflammatory cells. Regardless, once enlisted to degrade the surrounding matrix structure, the resulting milieu of cleaved peptides can then either facilitate or inhibit migration, proliferation, and invasion.²⁸

Although the molecular mechanisms regulating penetration of endothelial cells, including intravasation and subsequent extravasation, are unclear, these are certainly attributes that appear to be regulated by intercell signaling as well as cell-stroma interactions.¹⁵⁷ Similar to disruption of basement membrane and migration through extracellular matrix, ensuing invasion of endothelial layer to access the circulation is yet another limiting factor overcome by the unstable malignant neoplasm. Intravasation is the critical point at which the tumor cells can then circulate throughout the body, awaiting an opportunity to metastasize to distant organs. However, the overwhelming majority of cells released into the circulation are not able to effectively inhabit distant sites, as evidenced by animal models in which only one in 10,000 entering the circulation resulted in metastatic foci.¹⁵⁹ The question then arises regarding how malignant cells home in on the metastatic site of choice. For example, pulmonary involvement is relatively common with metastatic breast, gastrointestinal, and renal cancer as well as melanoma and sarcoma; liver spread is seen with metastatic foci from gastrointestinal, breast, and lung primary cancer; bone metastases arise from breast, lung, prostate, renal cell, and colorectal cancer.¹⁵⁹ An additional site that portends a dismal prognosis is distant spread to the brain, in which the circulating cancer cells must overcome the restrictions of the blood-brain barrier; this occurs with lung, breast, renal, and colon cancer as well as melanoma.¹⁵⁷

Recognizing that certain cancers have a predilection for certain locations unexplainable solely by circulatory patterns, preference for distant sites may be influenced by the tissue of origin, the developmental history, or even germline mutations. Therefore, permutations occur that are characteristic of the underlying malignancy. For instance, the proclivity of breast cancer spread to the lungs may be a result of increased Cxcr4 expression in the breast cancer cells matched to the lung tissue, which is replete with its respective ligand, Cxcl12.¹⁵⁷ Thus, a selective expansion of cells from an underlying tissue type with distinct genetic anomalies may allow transition from benign growth to invasive disease and consequent metastatic foci with a predilection toward locations conducive to colonization and further proliferation. However, elucidation of a specific mechanism will require continued investigation in both modeled systems and human studies. From this, we can gain a more in-depth understanding of the molecular mechanisms integral to metastasis.

Cancer Therapeutics

Although significant investigation regarding the underlying pathology involved in cancer formation has explicated many of the critical elements of transformation, pharmaceuticals based on these pathways are still being explored. Currently, surgical resection, chemotherapy, and radiation therapy are the modalities used for cancer treatment. Furthermore, the combined efforts of multiple individuals amassed in a multidisciplinary team are focused on the treatment of cancer. For instance, radiologists, medical oncologists, medical physicians, and surgeons (surgical oncologists) are responsible for intervention on behalf of the patient. By combining systemic treatment, either prior to, in conjunction with, or subsequent to local intervention (surgery, radiation), this team of physicians can attempt to render a cure. With improved treatment modalities, this task may be more easily accomplished.

The most widely used chemotherapeutics and radiation therapy trigger cell death by inducing DNA damage, blocking replication and division, and inducing significant cell stress in the hope that these effects will be more harmful to the malignant cells than the host. For instance, agents such as doxorubicin, 5-fluorouracil (5-FU), etoposide, actinomycin D, and irradiation promote DNA damage via various methods, ultimately activating the intrinsic apoptotic pathway and promoting cell death.¹⁰⁶ As discussed above, apoptosis is critical in both regulating overgrowth and determining response to therapy. However, recently, there has been increased attention devoted toward other mechanisms of cell death, such as mitotic catastrophe, autophagy, and necrosis, that occur during administration of therapeutics.¹⁰⁷ Unfortunately, regardless of the mechanism, these conventional options are limited as a result of toxicity and progressive resistance generated by the tumor cells. Therefore, new agents with higher potency and minimal systemic toxicity are necessary to overcome the current burden in cancer therapeutics.

Targeted therapies are now available demonstrating promising results and others in which efficacy is still being determined. For instance, molecules inhibiting RTKs in hematogenous and solid tumors, DNA breakpoint repair inhibitors in BRCA mutated tumors, and TRAIL agonists or antibodies for chemoradiation sensitization are all specific examples of directed therapy. Newer methods of combining

conventional therapy with directed therapy have been effective, such as rituximab with cyclophosphamide, hydroxydoxorubicin, vincristine (Oncovin), and prednisone (CHOP) in non-Hodgkin lymphoma; cetuximab in combination with 5-FU, oxaliplatin, leucovorin, and folic acid (FOLFOX-4) for metastatic colon or rectal cancer; or trastuzumab as an adjunct to doxorubicin/cyclophosphamide and paclitaxel in adjuvant chemotherapy for breast cancer. In addition to these currently implemented chemotherapeutics, we can begin to envision novel tumoristatic and tumoricidal agents that exploit many of the genetic changes attained by the tumor itself, for instance, combinations of specific therapies such as genetic fusion of recombinant TRAIL to tumor-specific CD19 antibodies to selectively navigate the drug to cancerous cells, as has been generated and subsequently used in patient-derived cell lines from acute B-lymphoblastic leukemia and B-CLL.^{106,160} An additional example is revealed by the use of recombinant TRAIL fused with EGFR transduction into mice with intraperitoneal renal cell carcinoma xenografts, resulting in significant tumor load reduction and increased long-term survival.¹⁶¹ These are a few examples illustrating the ingenuity in treatment that can be attained from furthering our understanding of malignant neoplastic disease. As evidenced by the progress encountered within the last decades, continued efforts toward the understanding of transformation from a benign to a malignant neoplasm with implementation of translational research and extensive clinical trials will provide further insight and superior methods to prevent and/or combat its negative sequelae.

Conclusion

In recent years, there has been an explosion in our understanding of the genetics involved in cancer. Through the depiction of requisite attributes necessary for malignant transformation, the model of multistep cancer formation arose.

Among these essential traits are sustained growth stimulation, disregard for inhibitory signals, indefinite replicative capabilities, avoidance of cell death, nascent vessel growth, and aggressive invasion with metastatic potential. As mentioned, the accrual of such traits to generate the multifaceted end product is by no means specifically sequential. Rather, these discrete attributes may be obtained in various points of evolution. Irrespective of the sequence, malignant cells have developed strategies in which to bypass the inborn protective mechanisms. Fortunately, through diligent investigation, clarification of certain aspects of the pathophysiology underlying tumor formation has been achieved. Notably, advancements continue and will allow further expansion of the current tumor model.

The introduction of new technologies such as improved imaging modalities and screening tools has enabled diagnosis of early-stage cancers, generating the possibility of treatment and cure. Additional advances, such as genome sequencing and other cell-specific techniques, such as microarrays with gene expression profiling, contribute toward characterization of candidate genes involved in tumorigenesis and give insight into prognosis through correlative studies. Advances such as these have furthered our understanding of the biology of cancer and resulted in new and improved therapies. We have entered a time period in which more specific and effective means of targeting tumor cells can be accomplished as opposed to generalized cell destruction. These therapies enhance tumor cell death while limiting normal cell toxicity. Targeting ligands, receptors, and downstream signaling molecules is currently implemented and has proven effective in various cancers. As we acquire a better understanding of the underlying mechanisms required for survival of malignant cells, therapies focused on preventive strategy may be feasible in the future.

28 CANCER IMMUNOLOGY

Clifford S. Cho, MD, FACS

At first glance, the ability of the immune system to recognize and eliminate a seemingly near-infinite array of potential viral or bacterial antigens may appear to stand in stark contradistinction to its seeming inability to do the same for foreign cancer antigens. This paradox has motivated intense efforts to understand the interplay between the immune system and cancer. The picture that has emerged from this investigation is that of a complex interaction that begins with a continuous process of immunologic surveillance for new cancer cells that is probably capable of eradicating many potential malignancies before they become clinically evident. Unfortunately, the onset of tumor progression underscores the fact that this equilibrium is often upset by escape mechanisms, through which some nascent tumors may overcome this immunologic control. Moreover, it has become apparent that growing cancers take advantage of a number of potentially immunosuppressive mechanisms to facilitate their growth and metastatic dissemination. Despite the sobering presence of such subversive mechanisms, the likely ability of the immune system to control many potential cancers highlights the optimistic possibility that therapeutic manipulation of this balance between cancer and host may allow us to harness the immune system as an effective means of treating established tumors.

This chapter addresses the following objectives:

1. To understand fundamental aspects of the immunologic response that have specific relevance to the interaction between the immune system and cancer
2. To examine the theorized processes of immunoediting (immune surveillance, immune equilibrium, and immune escape) that appear to characterize the interactive balance between emerging cancers and the host immune system
3. To explore current experimental immunotherapeutic strategies that have demonstrated promise as potentially novel treatments for patients with cancer

The Immunologic Response

Immune function is broadly divisible into two responses. The *innate immune response* can be thought of as an early and slightly indiscriminate process in which foreign antigens activate a number of cell types, such as macrophages and natural killer (NK) cells. Importantly, these cells are capable of direct cell killing but do not recognize specific foreign antigen; rather, they can be triggered by antibodies that bind and coat the surfaces of foreign tumor cells. Alternatively, NK cells are capable of indiscriminately binding to major histocompatibility complex (MHC) class I molecules that are expressed almost ubiquitously on the cell surfaces of most cell types, including cancer cells.

Because of their inability to recognize specific antigens, macrophages and NK cells are incapable of durable memory

against future encounters with antigen. However, as a result of their ability to induce cytolysis, foreign cells are degraded into various peptide fragments, which are then presented on MHC class I and class II proteins on the cell surfaces of macrophages. Thus begins an inflammatory cascade of events that eventually triggers the second type of immune response, known as the *adaptive immune response*. Unlike the innate response, the adaptive response is based on recognition of specific antigenic targets. The combination of peptide and MHC molecule provides a unique three-dimensional configuration that is recognized by a T cell receptor (TCR) expressed on specific T cells. Proper presentation of these foreign peptide antigens on class I MHC proteins activates CD8⁺ cytotoxic T lymphocytes (CTLs), and presentation of these peptide antigens on class II MHC proteins activates CD4⁺ helper T cells. Importantly, for this MHC-TCR stimulatory interaction to be productive, a number of so-called “costimulatory” ligand-receptor interactions must take place. If a full complement of these interactions takes place, CTLs and helper T cells specific for the antigen being presented by the macrophage become activated to recognize and eliminate that target antigen [see Figure 1]. However, if the costimulatory interactions are not fully engaged, these same antigen-specific T cells are rendered anergic, effectively programmed to ignore their cognate antigen [see Figure 2a].

The adaptive immune response may be further subdivided into two responses. The *cellular response* is initiated by this activation of T cell populations. Like NK cells, activated CTLs are capable of directly killing foreign cells; unlike NK cells, their cytolytic mechanisms are directed specifically at cells expressing the antigen peptide against which they have TCR specificity. This circular process of cell killing, antigen presentation, and T cell activation is augmented when antigen is presented to T cells by so-called professional antigen-presenting cells (APCs) such as mature dendritic cells (DCs); mature DCs are particularly effective at mediating T cell activation because of their rich expression of costimulatory ligands. Proinflammatory cytokines such as interleukin-2 (IL-2) and interferon gamma released by DCs and activated T cells further magnify the cellular response, resulting in the profound proliferative expansion of activated T cells. As might be expected, a number of physiologic regulatory controls exist to prevent excessive T cell activation. Activated T cells upregulate expression of a cell surface protein known as CTLA-4, which, when properly engaged, initiates the process of downregulating T cell activity [see Figure 2b]. In addition, populations of regulatory lymphocytes such as regulatory T cells (Tregs) and myeloid-derived suppressor cells (MDSCs) gradually increase after profound T cell activation and serve to downregulate T cell activity. The physiologic importance of these counterregulatory mechanisms is highlighted by genetic conditions where CTLA-4

Figure 1 (a) Proper activation of a CD8⁺ cytotoxic T lymphocyte (CTL) by an antigen-presenting cell (APC) requires the interaction of T cell receptor (TCR) with cognate antigen presented on major histocompatibility complex (MHC) class I proteins, as well as a complement of costimulatory molecule interactions. (b) Proper activation of a CD4⁺ T helper cell by APC requires the interaction of TCR with cognate antigen presented on MHC class proteins, as well as a complement of costimulatory molecule interactions.

or Treg activity is congenitally absent or weak; such conditions are typically characterized by exuberant autoimmune processes that are often fatal.

In the case of bacterial or viral infections, the profound proliferative expansion of activated T cells typically results in the clearance of the offending antigen(s). This expansion phase is then followed by a contraction phase, during which counterregulatory mechanisms induce apoptotic involution of activated T cell populations. Importantly, a subset of activated T cells persist and eventually differentiate into memory T cells, which are uniquely capable of prolonged survival (even in the absence of antigen stimulation) and rapid response to later encounters with antigen [see Figure 3].¹

The second component of the adaptive immune response is the *humoral response*, which is characterized by the release of soluble antibodies. Here, CD4⁺ helper T cells promote a lineage of immune cells known as B cells, which are capable of secreting large quantities of immunoglobulin antibodies that possess specificity against tumor antigens in their native, nonprocessed state. As outlined above, recognition and binding of foreign antigens with antibodies promote innate immune responses that are capable of killing cells expressing those antigens.

Immunoediting

Accumulating clinical observations and experimental data suggest that the interaction between cancer and the immune system is far from unidirectional or static. Rather,

there is increasing scientific momentum in favor of the theory of immunoediting.^{2,3} In this theory, it is speculated that emerging cancers elicit immunologic responses that modify the antigenic nature of cancer cells. Through this interaction, it is likely that the immune system is capable of arresting the progression of many cancers; however, it is also apparent that immunologically induced modifications and active counterregulatory mechanisms eventually allow some cancers the ability to overcome immunologic control. The evolutionary nature of immunoediting has been described as consisting of three phases: immune surveillance, immune equilibrium, and immune escape.

IMMUNE SURVEILLANCE

Tumor cells often express MHC class I molecules on their cell surfaces and can therefore evoke cytolytic NK cell responses. This innate immunologic response can result in tumor cell destruction, after which tumor antigens can be presented on macrophages and other APCs to induce cellular and humoral adaptive immune responses. Interestingly, it appears that humoral immune responses comprise a relatively minor proportion of the overall immune response to cancer. However, it is evident that tumor cells can elicit a cellular immune response directed at tumor-specific antigenic targets.

It might be expected that the high frequency of somatic genetic mutations occurring among rapidly dividing cancer cells would generate many novel immunogenic targets capable of recognition by the adaptive immune system.

Figure 2 (a) The absence of a full complement of costimulatory interactions, as might be present on an immature dendritic cell (iDC), results in the inhibition of T cells specific for the antigen being presented. (b) Engagement of CTLA-4 (whose expression is upregulated on the cell surfaces of activated T cells) by B7 serves to downregulate T cell function. (c) Downregulated expression of major histocompatibility complex (MHC) proteins on the surfaces of tumor cells is a mechanism of avoiding tumor antigen presentation and activation of potentially tumor-reactive T cells. APC = antigen-presenting cell; CTL = cytotoxic T lymphocyte; TCR = T cell receptor.

Indeed, a number of antigens have been defined with relative specificity for various cancers. Some of these are classifiable as oncoviral proteins, or antigens expressed by virus-associated cancers that are actually encoded within the genomes of oncogenic viruses. Examples of these are Epstein-Barr viral proteins also expressed in nasopharyngeal carcinomas, Burkitt lymphoma, and various lymphoproliferative disorders and human papillomavirus proteins expressed in

cervical carcinomas. Cancer/testis antigens are cancer proteins typically expressed in male gonadal germline cells but not expressed in normal tissues. Because gonadal germline cells lack MHC protein expression, germline cancer/testis antigens are not immunogenic; in contrast, the presence of MHC proteins on cancer cells renders these antigens potential targets for T cell-mediated recognition. An example of this is the cancer/testis antigen NY-ESO-1, which is expressed

Figure 3 (a) The kinetics of activated T cell homeostasis initiated by antigen encounter follow a predictable pattern of expansion of antigen-specific T cells, followed by antigen clearance and apoptotic contraction of antigen-specific T cells and ultimately resulting in the persistence of antigen-specific memory T cells capable of long-term immunologic protection from future encounters with antigen. (b) The kinetics of activated T cell homeostasis are fundamentally altered in the presence of cancer, with suppressed expansion and potentiated contraction resulting in the induction of smaller populations of memory T cells.

on a number of different malignancies, including melanoma, lung, and breast cancer. In contrast to these, differentiation antigens are normally expressed in differentiated tissues but are also expressed in malignancies derived from those differentiated tissues. For example, MART-1, gp100, and tyrosinase are proteins normally expressed in melanocytes that are also expressed in melanoma cells. In addition to expressing unique tumor antigens, cells that have undergone malignant transformation also overexpress naturally occurring ligands that may permit immune recognition. One example is NKG2D. Typically expressed on NK cells and various subsets of T cells, NKG2D receptors appear capable of recognizing NKG2D ligands that are overexpressed on a broad range of cancers; moreover, initiation of this receptor-ligand interaction appears to be capable of inducing tumor rejection under experimental conditions. Indeed, these interactions may provide a means by which the immune system can differentiate cancer cells from normal cells.

Ultimately, it is likely that some transformed populations of cells will be completely eradicated by these mechanisms of immune surveillance before ever becoming clinically apparent. It is hypothesized that other populations may avoid immune-mediated destruction and enter a phase of variable duration, during which they coexist within the confines of the immune system; this phase has been termed *immune equilibrium*.

IMMUNE EQUILIBRIUM

A number of mechanisms have been highlighted by which nascent tumors may overcome immunologic surveillance and maintain self-preservation. One such mechanism takes advantage of the high frequency of somatic mutations occurring within these rapidly dividing populations of cells. Mutations within genomic sequences encoding antigenic peptides may

produce enough variability in their conformational structures as to render previous antigen-specific T cell responses incapable of mediating immunologic control of these so-called antigen escape variants. This process, referred to as antigenic drift, can initiate a darwinian process of progressively diminishing tumor antigenicity.⁴ Another mechanism involves downregulated MHC class I expression as a means of limiting tumor antigen presentation. In this way, routine detection by NK cells and normal presentation of tumor antigens to the adaptive immune system are restricted, allowing tumors to avoid immune detection [see Figure 2c]. Indeed, a number of malignancies, including breast, gynecologic, colorectal, and renal cancers and melanoma, exhibit little to no MHC expression on their cell surfaces, often as a result of mutations that prevent proper intracellular transport or assembly of MHC subunit proteins.^{5,6}

The interaction between the immune system and evolving cancers does not end when cancer cells acquire a phenotypic alteration that allows them to elude immune detection. Rather, a dynamic equilibrium develops between evolving cancers and the constantly reacting immunologic milieu. With the onset of new mutations, clonal populations of a cancer possessing a particular form of immunologic resistance emerge and proliferate; in time, the ability of the immune system to adaptively respond to these new antigenic features controls their proliferative capacity, and the cycle continues. Indeed, accumulating evidence points to the existence of a process termed *immunosculpting*, in which the various pressures of the immune system gradually modify and shape the evolutionary development of malignancies. The experimental observation that tumors arising in immunodeficient mice are more immunogenic than tumors arising in immunocompetent mice demonstrates that cancer phenotype is, in large part, influenced by the immune system.⁷ Some tumors may

eventually succumb to complete immunologic clearance during this period of immune equilibrium. For others, it is possible that this phase of immune equilibrium may simply represent a period of tumor dormancy between the moment of initial tumorigenesis and the onset of clinically detectable disease progression. In these latter cases, it is evident that a subset of developing cancers acquires some critical phenotypic advantage that confers the ability to overcome the détente of immune equilibrium; this phenomenon has been termed *immune escape*.

IMMUNE ESCAPE

A critical accumulation of mechanisms through which transformed cells can elude immunologic detection and clearance may permit the unimpeded and exponential cellular growth that characterizes cancer. This phenotypic shift may be particularly evident among clonal populations of cancer cells that acquire the ability to undergo systemic dissemination, setting the stage for metastasis. In addition to this ability to elude immune surveillance, mechanisms that actively suppress potential antitumor immunologic responses appear necessary for tumor progression and dissemination. A number of such mechanisms have been elucidated. Tumor cells have been shown to express membrane-bound and soluble forms of Fas ligand (FasL), which can downregulate local immune responsiveness by inducing apoptosis of lymphocytes.^{8,9} In addition, many tumor cells are capable of secreting soluble quantities of inhibitory cytokines, such as transforming growth factor- β (TGF- β) and IL-10, as well as soluble NKG2D ligands and inhibitors, such as indoleamine 2,3-dioxygenase (IDO), which downregulate local NK and T cell responses.^{10–13} This profile of chemoattractants within the tumor microenvironment appears to promote a unique pattern of inflammatory conditions that paradoxically promotes tumor progression by favoring the leukocytic infiltration of tumor-associated macrophages (TAMs)^{14,15} and immature dendritic cells (iDCs).¹⁶ Although technically capable of presenting antigen to T cells, the absence of a full complement of costimulatory molecules expressed on iDCs promotes the abortive differentiation of naive T cells toward anergy and tolerance (unlike mature DCs, which promote T cell activation) [see Figure 2a]. The ability of TAMs to secrete inhibitory cytokines and downregulate T cell function also promotes tumor progression. Productive T cell activation is also suppressed by CD4⁺CD25⁺FoxP3⁺ Tregs and MDSCs, which are also found in accumulated quantities within the tumor microenvironment.^{17–19} As a result of these actively suppressive influences, the ability to generate an effective adaptive immune response against tumor antigens is thwarted, and tumor progression is facilitated.

The influence of cancer on T cell function is also exemplified in the altered kinetics of activated T cell homeostasis. Antigen-driven T cell proliferative expansion is weakened in the presence of cancer; moreover, apoptotic contraction is potentiated, resulting in the induction of smaller populations of memory T cells [see Figure 3].²⁰

Clinical Strategies in Cancer Immunotherapy

The ability of the immune system to initiate responses against tumor antigens and the ability to experimentally

promote immune-mediated killing of tumor cells *in vitro* give hope to the possibility that therapeutic interventions to augment the immune response could result in effective tumor control. Conceptually, the precise antigenic specificity of the immune response (by which unwanted side effects and collateral toxicities could be avoided) and the ability to generate durable immunologic memory (through which future cancer recurrences could be prevented) make immunotherapy an ideal form of cancer-directed treatment. To date, a number of strategies have been employed in an effort to actualize these theoretical benefits; although these have generally been met with limited successes, some examples of promise have emerged.

One approach has been to administer systemic or intratumoral doses of a general immunostimulant. Most commonly, stimulatory cytokines such as IL-2 or interferon alfa have been administered, but immunologic adjuvants such as bacillus Calmette-Guérin (BCG) are used for treating and preventing early bladder cancers. Clinical trials using IL-2 and interferon alfa for patients with high-risk melanoma have identified modest efficacy for patients with advanced melanoma and renal cell carcinoma.^{21–24} However, the incremental benefit and the prevalence of significant treatment-related toxicities have tempered enthusiasm for this treatment. A preliminary single-institution experience using systemic interferon alfa administered in an adjuvant setting for patients with resected pancreas adenocarcinoma has shown promising efficacy; the results await multicenter confirmation.^{25,26}

The ability of vaccine-based therapies to prevent a broad array of infectious diseases has generated great enthusiasm for cancer immunotherapy. Melanoma trials have been undertaken to study the potential efficacy of tumor antigen vaccines in engendering productive immune responses against melanoma cells.^{27,28} Although evidence for modest clinical benefit exists, it is apparent that vaccine-based efforts will likely require additional adjuncts to improve the immunogenicity of injected vaccines (immunostimulatory cytokines, loading of tumor antigens onto efficient APCs such as DCs, or tumor cells expressing costimulatory molecules or strongly antigenic epitopes) to augment their clinical efficacy.^{29–31}

Antibody-based cancer therapies have shown little promise in clinical investigation. As stated earlier, humoral responses to tumor cells do not appear to contribute significantly to the host response to cancer. However, systemic administration of blocking or depleting antibodies designed to interfere with the function of suppressive lymphocyte populations have shown some promise. To date, anti-CD25 monoclonal antibodies complexed to toxins designed to eliminate CD4⁺CD25⁺ Tregs have exhibited little benefit in augmenting immune responses against cancer.³² However, recent clinical trials using blocking antibodies against CTLA-4 (intended to prevent the autoregulatory suppression of activated T cells mediated by CTLA-4 engagement) have resulted in cases of impressive and durable tumor regression or control.^{33–35}

Adoptive cell-based strategies have been a particularly promising avenue of clinical investigation. In this approach, lymphocyte populations with potential reactivity against tumor antigens are harvested from patients with cancer, expanded *ex vivo*, and transferred in large quantities back into patients in the hope of inducing immunologic tumor

regression.³⁶ Recent efforts to harvest tumor-reactive T cell populations from tumor-infiltrating lymphocytes (TILs) have shown promise. In these strategies, TILs are harvested from resected tumors and activated and expanded in vitro using TCR stimulation and exogenous IL-2. Adoptive transfer of these activated populations of cells has resulted in significant and prolonged responses in a subset of patients with advanced melanoma.^{37,38} Depletion of host lymphocytes prior to adoptive transfer (using myeloablative chemotherapeutic agents or

lymphoid irradiation) appears to further enhance the efficacy of adoptive immunotherapy; it has been speculated that this improvement may be from enhanced in vivo expansion of tumor-reactive lymphocytes or from the elimination of potentially suppressive lymphocytes populations (e.g., Tregs) that could weaken the ability of adoptively transferred T cells to recognize and clear tumor cells.^{39,40}

29 PRINCIPLES OF CANCER TREATMENT

David F. Schneider, MD, MS, and Margo Shoup, MD, FACS

Multidisciplinary Care and the Surgical Oncologist

A multidisciplinary team approach to caring for cancer patients has become the benchmark in the modern era.^{1,2} This team involves oncologists, radiologists, pathologists, radiation oncologists, social workers, physical therapists, pharmacists, and surgeons. For most solid tumors, the best chance for a cure remains a complete surgical resection. The surgeon also plays a role in other phases of care, including obtaining tissue for a diagnosis, placing ports for chemotherapy, and palliation. In other words, the surgeon's role extends beyond cases of localized disease. For these reasons, the surgeon should play a prominent role on any multidisciplinary oncology team.² The following sections provide an overview of the various phases of caring for cancer patients along with the myriad modern treatment modalities.

Tumor Nomenclature

The broadest classification of neoplasms is the division between benign and malignant tumors. Benign tumors are designated by the *-oma* suffix and lack the normal cell cycle or growth regulation but do not invade through tissue layers or into surrounding organs. Malignant tumors, or cancers, do invade adjacent tissue layers. The tissue of origin determines the nomenclature of malignant tumors. Carcinomas are malignancies derived from epithelial tissues, whereas malignant neoplasms arising from mesenchymal tissues are termed sarcomas. Histology further subdivides cancers. Tumors cells that form glandlike structures are adenocarcinomas and include the most common cancers of the gastrointestinal tract and breast. When tumor cells organize as a squamous epithelium, they are called squamous cell carcinomas. Blastomas originate from embryonic tissues.³

TUMOR GRADE

The degree of cellular differentiation among cancer cells determines the tumor's grade. Many cancers have separate pathologic grading systems incorporating such factors as nuclear pleomorphism, necrosis, nucleus-to-cytoplasm ratio, necrosis, and number of mitoses. In general, a cancer's stage holds more prognostic value than its grade, but in certain cancers, such as sarcomas, the grade holds more significance. Finally, cancers are termed undifferentiated when the tissue of origin or histologic type cannot be determined, and this usually portends a poor prognosis.

TUMOR STAGE

In most cancers, the tumor stage usually determines a cancer's treatment and prognosis. Clinical staging relies on

noninvasive testing such as imaging studies or physical examination findings, whereas pathologic staging depends on histologic findings in resected tumor specimens. Pathologic staging is more reliable than clinical staging because it evaluates microscopic spread of disease that imaging cannot determine.

The American Joint Committee on Cancer (AJCC) has provided the most widely used staging system.⁴ It is based on the TNM classification, with *T* referring to tumor size, *N* referring to regional lymph nodes, and *M* referring to distant metastatic spread of cancer. *T* stage ranges from 0 to 4, with higher numbers referring to larger size or increasing level of invasion. Regional lymph nodes are classified from N0 to N3, with increasing number of involved lymph nodes. M0 indicates no metastatic disease, whereas M1 and M2 denote various levels of distant metastatic spread. Various combinations of *T*, *N*, and *M* categories comprise stages from 0 to IV, with higher stages representing increasingly widespread cancer and poorer prognosis.^{3,4}

Initial Evaluation of Cancer Patients

TISSUE DIAGNOSIS

As with all disease processes, the initial evaluation of cancer patients should begin with a complete history and physical examination. The surgeon's involvement often begins with obtaining tissue for diagnosis to complete the pathologic staging. There are several types of tissue biopsy, each uniquely suited for different types of cancer or location.

Regardless of the biopsy technique, the surgeon must follow certain principles to ensure a good oncologic result. First, achieving good hemostasis is imperative; hematomas make subsequent dissection more difficult and can allow tumor cells to spread along the plane of the hematoma. Second, any needle tract or incision should be oriented such that it can be included in subsequent resection of the entire specimen.⁵

Fine-Needle Aspiration Biopsy

Palpable tumors close to the skin surface can be easily sampled with a thin needle using local anesthesia in the office setting. Lymph nodes, thyroid nodules, and breast masses are well suited for this biopsy technique. Even masses that are too small or too deep to palpate can be evaluated with fine-needle aspiration biopsy (FNAB) by using computed tomography or ultrasound guidance. The main limitation of FNAB is that it only provides cells for evaluation by a cytopathologist; it does not provide histologic or architectural information about the tumor. Therefore, it will not differentiate between invasive or in situ cancers. Given that FNAB

uses a thin needle, sampling errors may occur in larger tumors.

Core-Needle Biopsy

Core-needle biopsy can also be done in the office setting under local anesthesia. It uses a larger needle that excises a thin cylinder of tissue, allowing the pathologist to interpret more histologic information from the tissue architecture. This technique is often used to evaluate breast, prostate, and liver lesions and sometimes sarcoma.⁵

Excisional Biopsy

Excisional biopsy removes the entire gross tumor. This technique is employed when a larger tissue sample is needed for accurate diagnosis or grading. The entire lesion is excised without removing adjacent structures. If this is not possible, then incisional biopsy is appropriate.⁵

Incisional Biopsy

Incisional biopsy removes a portion of a tumor, but it is not completely excised. This technique is appropriate when excisional biopsy is not possible because of involvement of adjacent organs or when the tumor is too large for complete excision. For example, extremity sarcomas that are greater than 5 cm should undergo incisional rather than excisional biopsy. In this case, the incision should be made longitudinally such that the entire scar can be removed during subsequent resection.⁵

Staging Operations

Less common in the modern era, surgeons are sometimes asked to perform operations to stage Hodgkin disease. In lung cancer and laryngeal cancer, the operation itself determines the stage. For example, in lung cancer, lymph nodes from each mediastinal station are sampled at the time of lobectomy or pneumonectomy to determine the tumor's stage.⁶ Laparoscopy is often performed as the initial maneuver in operations for gallbladder, gastric, or pancreatic cancer to determine the extent of disease within the abdomen.^{7,8} The presence of widespread tumor deposits or liver metastases can save patients from a more morbid laparotomy when there is little chance for cure.⁸

Principles of Surgical Therapy

For most solid tumors, the best chance of a cure remains a complete surgical resection. Operating for a cure, however, is not the only reason to operate on cancer patients. Staging, cytoreduction, or palliation may also be achieved with surgical therapy. The surgeon, in conjunction with the multidisciplinary team and the patient, should clarify the purpose of any operation before it is undertaken.²

CURATIVE SURGERY

Operating for a cure usually refers to removing the entire primary tumor with a margin of normal tissue to prevent local recurrence. Each tumor type requires a different distance of disease-free margins to minimize the chance for local recurrence. Margins are classified based on their degree of macroscopic or microscopic disease. An R0 resection is the most oncologically desirable margin, with no gross or

histologic evidence of disease. An R1 resection is defined as no residual gross disease but positive microscopic residual disease, whereas an R2 resection leaves residual gross disease after surgery and should prompt further resection if the goal of surgery is to cure.⁴

To achieve an R0 resection, often adjacent organs are resected with the tumor, in an en bloc resection. Any fixation or adherence to adjacent tissues or organs is considered malignant in nature; therefore, en bloc resection should be performed. In these situations, the surgeon should balance the extent of resection with the patient's functional status. In many cancers, modern data have demonstrated that a more limited approach is oncologically equivalent but functionally and/or cosmetically desirable. Examples include breast conservation, sphincter-sparing rectal surgery, or limb-sparing surgery for sarcoma.⁹

Multidisciplinary Care in Curative Surgical Therapy

A balance between extent of resection and functional or cosmetic outcome can also be modified by knowledge of other modalities that might be employed to achieve a cure. For example, postoperative radiation therapy has allowed breast conservation therapy and equivalent oncologic results. In this example, the use of postoperative radiation does not eliminate the need for adequate surgical margins but does allow for a more cosmetic result. When chemotherapy or radiation is used after the primary treatment (surgical therapy), it is referred to as an adjuvant therapy.²

When these other modalities are used in the preoperative setting, they are called neoadjuvant therapies, and this has revolutionized the care of certain tumors, such as esophageal and rectal cancers or liver metastases from colorectal cancer, because neoadjuvant therapy can potentially convert unresectable tumors into resectable ones, making a complete cure possible. Neoadjuvant therapy can also limit the extent of surgery that would otherwise have been necessary to achieve negative margins.^{2,10}

Regional Lymph Nodes

For most solid tumors, the regional lymph node basin is the first and most prevalent site of metastasis. The status of the regional lymph node basin provides staging information and can extend local control of tumor. For this reason, regional lymph node dissection or sampling is often performed at the time of curative resection.

Elective lymph node dissection refers to removal of clinically negative lymph nodes in the same setting as resection of the primary tumor. This is often part of curative surgery for most gastrointestinal, urologic, and head and neck malignancies. Performing a lymphadenectomy only when a patient has clinically positive lymph nodes is referred to as a therapeutic lymph node dissection.¹¹ Performing a lymph node dissection on clinically negative nodes obviously adds morbidity. For breast cancers and melanoma, the adoption of sentinel lymph node biopsy has allowed the ability to stage regional lymph nodes and select patients who would benefit from a complete lymph node dissection.¹² In this technique, radioactive tracers and/or dye are injected around the primary tumor and then mapped to regional lymph node basins. The first, or "sentinel," lymph node to take up the dye or tracer is then evaluated for the presence of cancer cells, guiding further lymph node dissection.^{5,13}

PALLIATIVE SURGERY

Patients whose cancer is unresectable often suffer from pain, bleeding, obstruction, malnutrition, or infection. The surgeon can relieve these problems, improving quality of remaining life.¹⁴ Palliative surgery includes bypass operations, stents, partial resection, and feeding tubes.¹⁵ Not all patients with advanced cancer are candidates for palliative surgery. It is very difficult to make asymptomatic patients feel any better. Furthermore, the surgeon must balance any potential benefit of a palliative procedure with the potential morbidity.¹⁶ Palliation is another area that should be considered a multidisciplinary approach as there are often medical or minimally invasive approaches that might benefit patients whose operative risk is unacceptably high. Radiation and chemotherapy can also be used in a palliative fashion.^{12,15}

PROPHYLACTIC SURGERY

Although genetic lesions play a role in the development of all cancers, the advent of genetic testing has focused much attention on heritable forms of cancer. Highly penetrant mutations in specific genes are associated with familial syndromes such as the Li-Fraumeni syndrome (breast cancer), multiple endocrine neoplasia (MEN) types IIA and IIB (medullary thyroid cancer), and hereditary nonpolyposis colorectal cancer (HNPCC).¹⁷ In addition, patients with chronic inflammatory conditions are known to be at high risk for malignant transformation. Surgical therapy is directed at removing the organ at risk once such genetic mutations or inflammatory conditions are identified. As with any surgery, the risk of any prophylactic surgery and its associated morbidities must be weighed against any potential benefit. Alternatives to surgery will involve a lifetime of close surveillance of the organ at risk. The surgical oncologist therefore must have a thorough understanding of genetics and the inherited risk for each particular inherited syndrome; a detailed discussion of the risks and benefits of prophylactic surgery should be undertaken with each patient.¹⁷ Table 1 contains inherited cancer syndromes for which prophylactic surgeries are performed.

CYTOREDUCTIVE SURGERY

Certain cancers tend to be widespread throughout the abdomen at the time of diagnosis. In these situations, there is benefit to removing as much of the tumor deposits as possible (i.e., “debulking”). This technique is often combined with radiation, chemotherapy, or intracavitary chemotherapy.¹⁸ In other cases, reducing the tumor burden improves the effectiveness of chemotherapy or reduces symptoms. Examples of cancers where a cytoreductive approach has been shown to be helpful include ovarian, peritoneal mesothelioma, neuroendocrine tumors, and pseudomyxoma peritonei.¹⁹

Principles of Cancer Pharmacology

GUIDING CONCEPTS

Tumors arise from our own native tissues. Therefore, pharmacologic targeting of cancer cells is difficult, and most chemotherapeutic agents have a very narrow therapeutic index. The major difference between neoplastic and nonneoplastic cells is the rate of cell division. Many drugs exploit this

fact and kill actively proliferating cells or are classified as cell cycle specific. In contrast, other drugs can kill cells that are not actively dividing at the time of exposure, and these agents are called cell cycle nonspecific. To achieve maximal cell killing, most chemotherapy protocols use combination therapy with multiple agents, each with a different mechanism of action. Only a fraction of cancer cells, the growth fraction, will be susceptible to chemotherapy at any given time. Therefore, most chemotherapy regimens rely on repeated dosing for maximal cell killing. Because of the narrow therapeutic index, the dosing interval usually depends on the regrowth and repair of normal tissues.³

Chemotherapy failures have multiple etiologies, including excessive tumor burden and inadequate drug delivery to the tumor. Drug resistance also plays a large role in chemotherapy failure. Although several mechanisms of tumor resistance are known, the multidrug resistance (*MDR*) gene encodes a protein that actively pumps many chemotherapy drugs out of tumor cells.²⁰ Given that genetic mutation is the underlying cause of all cancer, continued mutation may alter the protein targets of chemotherapy agents. Similarly, overproduction of a target protein can overwhelm the drug dose. Mutations that confer increased capability of DNA repair can cause failure of DNA alkylating or binding agents. Oncologists can overcome tumor resistance with combination chemotherapy. Prompt recognition of failure and altering the regimen can also prevent overt failure.

Certain toxicities are common to almost all chemotherapeutic agents because they target rapidly dividing cells, including nonneoplastic cells of the bone marrow or gastrointestinal tract. Therefore, common toxicities include diarrhea, nausea, vomiting, mucositis, alopecia, and myelosuppression.³

CLASSES OF CHEMOTHERAPY AGENTS

DNA Alkylating and Cross-linking Agents

These agents work by transferring alkyl groups to DNA, resulting in DNA strand breaks, cross-linking of DNA, or miscoding of DNA strands during cell division. Examples of agents in this class are nitrosoureas (carmustine, semustine, lomustine), cyclophosphamide, chlorambucil, dacarbazine, and procarbazine. They are effective for hematologic malignancies in addition to breast, lung, and endometrial cancers and melanoma. The most common adverse reactions are myelosuppression and hemorrhagic cystitis.¹²

Platinum Analogues

Similar to the DNA alkylating agents, platinum analogues bind DNA, forming intra- and interstrand cross-links that inhibit DNA synthesis and transcription. Examples include cisplatin, carboplatin, and oxaliplatin. Toxicities with these agents include myelosuppression, hemolytic-uremic syndrome, electrolyte abnormalities, and neuropathy. Platinum agents are used to treat colon, rectal, breast, gastric, esophagus, testicular, gynecologic, and head and neck cancers.^{3,21}

Antimetabolites

These drugs are analogues of nucleic acids or their precursors, and they work by becoming incorporated into the cell's nucleic acids. Antimetabolites can also bind the enzymes

Table 1 Prophylactic Surgery for Inherited Cancer Syndromes

Syndrome	Genetic Defect	Cancer(s)	Inheritance Pattern	Prophylactic Surgery(ies)	Associated Abnormalities
Hereditary breast cancer	<i>BRCA1</i> <i>BRCA2</i>	Breast, ovarian	Autosomal dominant	Bilateral mastectomy/ nipple-sparing mastectomy, bilateral salpingo-oophorectomy	Male breast cancer, prostate and pancreatic cancers
Li-Fraumeni syndrome	Germline <i>p53</i> mutation	Breast	Autosomal dominant	Bilateral mastectomy/ nipple-sparing mastectomy	Sarcomas, brain tumors, acute leukemias, adrenal cortical carcinomas
Cowden disease (multiple hamartoma syndrome)	Germline <i>PTEN</i> mutation	Breast, thyroid	Autosomal dominant	Bilateral mastectomy/ nipple-sparing mastectomy	Skin/mucous membrane hamartomas, endometrial cancer, renal cancers, Lhermitte-Duclos disease, glycogenic acanthosis of the esophagus
Familial adenomatous polyposis (FAP)	Germline mutation in <i>APC</i> gene	Colorectal	Autosomal dominant	Total proctocolectomy with permanent ileostomy, total colectomy with ileorectal anastomosis + surveillance, total proctocolectomy with ileal pouch anal anastomosis	Desmoids, duodenal, periampullary adenomas
Hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome)	Germline mutation in DNA mismatch repair (MMR) genes (<i>hMLH1</i> , <i>hMSH2</i> , <i>hMSH6</i> , and <i>PMS2</i>) or microsatellite instability (MSI)	Colorectal	Autosomal dominant	Segmental colectomy + surveillance, total colectomy with ileorectal anastomosis + surveillance, total proctocolectomy with ileal pouch anastomosis	Endometrial, ovarian, small bowel, ureter, or renal pelvis cancers
Multiple endocrine neoplasia (MEN) Type IIA	Germline mutation in <i>RET</i> proto-oncogene	Medullary thyroid	Autosomal dominant	Total thyroidectomy, central cervical lymph node dissection, subtotal parathyroidectomy with autotransplantation	Pheochromocytoma, hyperparathyroidism, cutaneous lichen amyloidosis, Hirschsprung disease
Type IIB	Germline mutation in <i>RET</i> proto-oncogene	Medullary thyroid	Autosomal dominant	Total thyroidectomy, central cervical lymph node dissection	Pheochromocytoma, neural gangliomas, megacolon, skeletal abnormalities, enlarged peripheral nerves
Familial medullary thyroid cancer (FMTC)	Germline mutation in <i>RET</i> proto-oncogene	Medullary thyroid	Autosomal dominant	Total thyroidectomy, central cervical lymph node dissection	

involved in nucleic acid production, thereby halting the cell's synthetic or dividing capability. Examples include methotrexate, mercaptopurine, thioguanine, and cytarabine. These drugs are used primarily for hematologic malignancies and colorectal cancers.²² Fluorouracil is an antimetabolite used for gastrointestinal malignancies. Skin rashes, myelosuppression, neuropathy, nausea, and vomiting are among the toxicities.³

Antimicrotubule Agents

This class of drugs includes plant-derived compounds that bind tubulins, obstructing the assembly of microtubules in the mitotic spindle and resulting in mitotic arrest in metaphase. Vinca alkaloids such as vinblastine and vincristine

inhibit tubulin polymerization and are used for hematologic malignancies and breast and lung cancers. Taxanes (paclitaxel and docetaxel) block tubulin depolymerization and are used to treat ovarian, breast, lung, and bladder cancers.²³ These drugs cause myelosuppression, weakness, peripheral neuropathy, and hypersensitivity reactions.

Topoisomerase Inhibitors

Two topoisomerase enzymes (I and II) function to maintain DNA strands, making transient single- or double-strand nicks in DNA to correct any alterations in topology that occur during replication or transcription. Inhibition of the topoisomerase enzyme(s) causes structural DNA damage. They are cell cycle specific, exerting their effects on rapidly

proliferating cells.²⁴ These drugs are used to treat hematologic malignancies and lung, prostate, bladder, colorectal, and testicular cancers. Etoposide, teniposide, and topotecan cause myelosuppression and diarrhea.

Antibiotics

Antibiotics are drugs derived from fungus that interfere with nucleic acid synthesis by intercalating DNA, blocking synthesis, and inducing strand breakage. Examples include doxorubicin, which causes cardiomyopathy. Bleomycin, used for testicular cancer, causes interstitial pulmonary fibrosis.¹²

Agents Targeting Epidermal Growth Factor Receptors

This class of agents exemplifies targeted therapy because they are used in patients whose cancer over-expresses a particular epidermal growth factor receptor (EGFR).^{3,25} Molecular diagnostics allow testing for overexpression or mutation of native receptors; antibodies or other small molecules can then be administered to block these receptors.

Trastuzumab is an IgG antibody that binds the extracellular domain of the Her-2/neu receptor, an EGFR with an intracellular tyrosine kinase. Breast cancers that express this Her-2/neu receptor exhibit increased proliferation, metastatic potential, and resistance to other therapeutic agents. Binding of trastuzumab to the Her-2/neu receptor diminishes downstream signaling, allowing cytotoxic chemotherapies to become effective.^{25,26}

Cetuximab is another antibody that binds EGFR, blocking the signaling events that lead to proliferation. It also enhances the effect of cytotoxic chemotherapies, blocks angiogenesis, and promotes apoptosis. If, however, a tumor has a K-ras mutation, it will not respond to cetuximab. This agent is used primarily in advanced colorectal cancer.

Bevacizumab

The vascular endothelial growth factor (VEGF) promotes angiogenesis and has become an anticancer target because tumors must develop their own blood supply for survival. Although it does not require a specific diagnostic test, many also consider bevacizumab a targeted therapy because it is a monoclonal antibody specific to the VEGF mechanism.³

Imatinib Mesylate

Imatinib is an adenosine-triphosphate inhibitor of *bcr-abl*, platelet-derived growth factor receptor, and *c-kit* tyrosine kinases. This drug is a small-molecule targeted therapy that is highly effective against gastrointestinal stromal tumors and Philadelphia chromosome-positive chronic myelogenous leukemia.²⁷

Hormonal Therapy

Hormones control the growth and differentiation of certain tissues. Modulation of the effect of sex hormones on prostate, uterus, and breast cancers has become a primary treatment modality or part of palliative care.

Selective estrogen receptor modulators This class of drugs mimic the structure of estrogen and binds to the estrogen-receptor complex. The effect varies depending on

the target tissue because these drugs can act as proestrogenic in some tissues while inhibiting the effect of estrogen in others. Tamoxifen is the most well-known example that is used to treat estrogen receptor-positive breast cancers or in women who are at high risk for developing breast cancer.²⁸ Because tamoxifen acts like estrogen in the uterus and blood vessels, patients taking tamoxifen are at higher risk for uterine cancer and deep vein thrombosis.¹²

Aromatase inhibitors The enzyme aromatase converts adrenal steroids to estrogen in fat cells. Therefore, postmenopausal women still produce some estrogen even though their ovaries are inactive. Anastrozole, a selective aromatase inhibitor, can treat metastatic breast cancer or be an adjuvant therapy in postmenopausal women whose breast tumors are positive for estrogen or progesterone receptors²⁹; anastrozole can also be given for prevention in high-risk patients.

Immunotherapy

Cancer cells evade immune response by a variety of mechanisms. Newer therapies either augment natural immune responses to tumor cells or train the immune system to attack tumor cells that would otherwise evade immunologic recognition.

PASSIVE IMMUNOTHERAPY

Passive immunotherapy involves the administration of monoclonal antibodies or cells. Monoclonal antibodies can be used as cancer therapy when they target tumor-specific antigens. These antibodies can be developed and purified in a laboratory and then administered to patients. Another form of passive immunotherapy isolates tumor-infiltrating lymphocytes from patient samples, cultures them in the presence of interleukin-2 (IL-2), and then administers these cells back to the patient. These lymphocytes are often manipulated prior to readministration to augment their tumor antigen recognition or cytolytic potential. Many such forms of adoptive immunotherapy are currently under investigation.³⁰

ACTIVE IMMUNOTHERAPY

Nonspecific forms of immunotherapy do not target particular tumor antigens. Rather, they include a variety of mediators, such as cytokines and interferons, that nonspecifically activate the immune system. Examples include IL-2, interferon alfa, and interferon gamma.¹²

Specific active immunotherapy refers to cancer vaccines where specific peptide antigens or autologous tumor cells are administered to patients in the hope of stimulating immune responses directed at their tumor. The single-peptide strategy has had only limited success for melanoma. Using the patient's own tumor cells as an autologous tumor cell vaccine avoids the technical complexities of choosing the ideal peptide that will be expressed by all patients suffering from a particular cancer and that will become displayed on HLA molecules. Currently, a variety of autologous tumor vaccines are under investigation.³⁰

31 EVALUATION OF SURGICAL RISK, INCLUDING CARDIAC AND PULMONARY RISK ASSESSMENT

Madhuchhanda Roy, MD, PhD, Barbara Zarebczan, MD, and Sharon Weber, MD, FACS

All surgical procedures are associated with the risk of perioperative morbidity and mortality. Appropriate preoperative medical evaluation should assess whether a patient has a higher than average risk of having a surgical complication based on his or her current health status. The rationale behind preoperative risk assessment is to systematically address the patient's preexisting medical conditions and identify unrecognized comorbidities, thereby treating potential complications prior to surgical intervention. The risk assessment, although specific to the patient's condition, must also take into account the surgical procedure to be performed and the type of anesthesia to be administered. Preoperative evaluation also provides a medical plan that helps patients and their primary care physicians, anesthesiologists, and surgeons make the best treatment decisions regarding short-term and long-term clinical outcomes.

To properly evaluate surgical risk, a thorough history and physical examination are paramount not only to assess the state of a patient's preexisting medical condition but also to identify unrecognized disease processes. Laboratory tests should then be ordered to supplement the initial evaluation and most commonly include a complete blood count, electrolyte measurements, blood glucose, tests of renal and liver function, and coagulation studies. Diagnostic testing can also be directed at evaluating specific comorbidities, such as echocardiograms and stress tests in a heart failure patient and pulmonary function tests in a patient with chronic obstructive pulmonary disease (COPD). Once a patient has been fully evaluated, interventions can be initiated to ensure that all steps are taken to minimize the risk of surgery and provide for a satisfactory outcome for both the patient and the physicians involved in his or her care.

Cardiac Risk Assessment

Postoperative cardiac complications are a major cause of morbidity and mortality in surgical patients. The latest guidelines from the American College of Cardiology (ACC) Foundation and the American Heart Association (AHA) Task Force on Practice Guidelines, published in 2007, focus on the evaluation of patients undergoing noncardiac surgery who are at risk for perioperative cardiac morbidity and/or mortality.¹

PREOPERATIVE EVALUATION

According to the ACC/AHA guidelines, to determine the risk of cardiac events, patient-specific clinical variables,

exercise capability, and surgery-specific risk factors should initially be reviewed.¹ The evaluating physician should gather information from the patient's history, physical examination, and electrocardiogram (ECG) as an initial screen to assess the risk of perioperative cardiac complication.

History

A careful and meticulous history of the patient's past and present symptoms, clinical course, and exercise capability is of the utmost importance in evaluating surgical risk. The preoperative evaluation may often be the first cardiovascular assessment for a patient; therefore, symptoms of angina or dyspnea on exertion suggestive of cardiac disease may be diagnosed for the first time. The initial preoperative evaluation should specifically inquire about any previous history of heart disease, including stable or unstable angina, myocardial infarction (MI), heart failure, aortic stenosis, severe hypertension, and peripheral arterial disease.

Exercise Capability

A patient's exercise capability is an essential tool to assess general perioperative risk; patients with higher exercise tolerance usually have lower risk and vice versa. Various activity scales based on a set of questions are used to determine a patient's functional capacity [see Table 1].² Simple questions, such as if the patient is able to walk two blocks on level ground or carry two bags of groceries up one flight of stairs without symptoms, can provide a rough estimate of the patient's cardiac risk. These activities are approximately four metabolic equivalent of tasks (METs). Patients who are able to carry out these activities in their daily routine generally are at low risk for suffering major postoperative complications.³⁻⁵ In contrast, patients with poor exercise capability who are unable to perform these simple tasks have a higher incidence

Table 1 METs Assessment

- Can take care of self, such as ambulate, eat, dress, or use the toilet (1 MET)
- Can walk up a flight of steps or up a hill (4 METs)
- Can do heavy work around the house (scrubbing floors or lifting or moving heavy furniture; between 4 and 10 METs)
- Can participate in strenuous sports (swimming, football, basketball, tennis, and skiing; > 10 METs)

The metabolic equivalent of tasks (METs) expresses the rate of energy consumption for given activities, with 1 MET defined as 3.5 mL O₂ uptake/kg per min, the resting oxygen uptake in a sitting position. METs can be used to assess a patient's functional capacity.

of serious postoperative cardiac complications. However, it is important to consider the presence of physical disabilities or peripheral arterial disease that might limit a patient's capability to perform such simple tasks and thus make this part of the evaluation unreliable.

Physical Examination

The overall appearance of a patient provides important evidence regarding his or her clinical status. Cyanosis, pallor, dyspnea with minimal activity, poor nutritional status, obesity, and anxiety are potential clues of underlying cardiovascular disease that may need immediate attention and management. A cardiovascular physical examination of the patient must include measurements of blood pressure in both arms, inspection of jugular venous pulsations for any abnormalities, and palpation and auscultation of the carotid arteries for the presence of bruits. Precordial auscultation evaluates any abnormal heart sounds or murmurs. Abnormal heart sounds or murmurs may be indicative of heart failure or valvular stenosis, which increase perioperative risk. Although significant atrial or mitral stenosis increases the risk of heart failure, aortic and mitral regurgitation put a patient at increased risk for developing infective endocarditis in the setting of bacteremia following surgery; hence, prophylactic antibiotics should be considered in these circumstances.⁶ The presence of an implanted pacemaker indicates a need for detailed cardiac evaluation and testing. A thorough cardiovascular examination should also include auscultation of the lungs and examination of the extremities to check for edema and the presence of palpable peripheral pulses. The presence of peripheral vascular disease should raise the suspicion of possible coronary artery disease (CAD).

Resting Electrocardiogram

The 2007 ACC/AHA guidelines on perioperative cardiovascular evaluation recommend a resting 12-lead ECG in patients with known cardiovascular disease, peripheral arterial disease, or cerebrovascular disease.^{1,7} Although the presence of a significant ST segment change or a Q wave is known to be associated with an increased incidence of perioperative cardiac complications, a more recent retrospective study of preoperative ECGs compared with clinical characteristics suggests an association of right or left bundle branch block with perioperative MI and left bundle branch block with perioperative mortality.^{8–10}

Stress Testing

Recommendations for preoperative stress testing are based on the individual's clinical risk factors, functional capacity, and procedure-specific risk. The 2007 ACC/AHA guidelines advocate stress testing for patients who are at high risk (three or more revised cardiac index criteria) and have poor functional capacity (less than four METs) who are undergoing vascular surgery when the results of such testing can direct management [see Table 2].¹¹ Routine stress testing is not required in patients with at least one clinical risk factor and poor functional capacity (less than four METs) who are scheduled for intermediate-risk surgery or in patients with at least one clinical risk factor but good functional capacity (four or more METs) who are scheduled for vascular surgery.

Table 2 Revised Cardiac Risk Index to Predict Major Cardiac Risk Associated with Surgery

Independent predictors of major cardiac risk	
1. High-risk surgery (intraabdominal, intrathoracic, or suprainguinal vascular surgery) 2. Ischemic heart disease (MI, positive treadmill test, current chest pain, nitroglycerin therapy, pathologic Q waves on ECG) 3. Congestive heart failure (documented history, pulmonary edema, paroxysmal nocturnal dyspnea, pedal edema, S₃ heart sound, chest x-ray with pulmonary vascular redistribution) 4. Cerebrovascular disease (TIA/CVA) 5. Diabetes mellitus requiring insulin therapy 6. Renal failure (preoperative serum creatinine > 2.0 mg/dL (177 μmol/L))	
No. of Risk Factors	Risk, % (95% CI)
0	0.4 (0.1–0.8)
1	1.0 (0.5–1.4)
2	2.4 (1.3–3.5)
3+	5.4 (2.8–7.9)

CVA = cerebrovascular accident; ECG = electrocardiogram; MI = myocardial infarction; TIA = transient ischemic attack.

Patients who are not limited by claudication or orthopedic degenerative joint disease and are able to exercise adequately to reach the acceptable target heart rate can undergo exercise ECG testing. Patients with limited mobility should undergo pharmacologic stress testing with either dipyridamole-thallium radionuclide myocardial perfusion imaging or dobutamine stress echocardiography based on availability and expertise as well as the patient's needs.¹²

In a review of five large studies of thallium perfusion imaging, stress testing has a 90 to 100% negative predictive value for postoperative cardiovascular events but only a 6 to 67% positive predictive value.^{5,13} Thus, stress testing is very useful for decreasing estimated risk when found to be negative or normal. Notably, however, even a negative stress test does not ensure that perioperative cardiac events will not occur, and patients and physicians need to be aware of this.

Resting Echocardiography

Routine echocardiography is not recommended. However, a resting echocardiogram should be obtained to measure the extent of valvular dysfunction in patients with a murmur. It is also helpful in evaluating the degree of ventricular dysfunction, dyspnea of uncertain etiology, and cardiac causes of pulmonary hypertension.^{13,14}

Preoperative Revascularization

Very few noncardiac surgery patients require preoperative cardiac catheterization and revascularization.¹⁵ Using the approach described in the ACC/AHA guidelines, three independent studies found that coronary angiography is performed in only two to 11 patients and even fewer preoperative revascularizations are performed.^{16–18} Given that these studies included symptomatic patients who were more likely to undergo revascularization, an even lower rate of intervention in asymptomatic patients could be expected; hence,

routine preoperative revascularization is not indicated.¹⁵ However, to date, there is no clear evidence that revascularization improves perioperative outcome.^{19,20}

PATIENT-RELATED RISK FACTORS

Patient risk factors such as unstable or severe angina, recent MI, severe stenotic aortic or mitral valvular disease, decompensated or worsening heart failure, and significant arrhythmias are considered major predictors of perioperative cardiac complications, warrant intensive management, and potentially delay or cancel elective surgical procedures.¹ Overall, these predictors can be deduced from a careful history and physical examination combined with a resting ECG and can help direct the clinician regarding further evaluation and aggressive management as needed.

Coronary Artery Disease

The presence of CAD is evident in patients with a history of acute MI, coronary angioplasty, or coronary artery bypass grafting (CABG) or in patients with a coronary angiogram demonstrating luminal occlusion or irregularity. Yet many patients with severe double- or triple-vessel disease lack any clinical evidence of CAD as a result of atypical presentations or functional limitation resulting from advanced arthritis or peripheral vascular disease. A few of these patients may benefit from noninvasive revascularization independent of planned noncardiac surgery; however, recent data suggest a limited value to coronary revascularization before noncardiac surgery in the majority of patients.²¹ Advanced age also puts patients at increased risk because of a higher likelihood of CAD and the presence of an aging myocardium. The mortality of acute MI has been demonstrated to be significantly higher in the elderly population perioperatively.^{10,22–24} Gender also plays a key role in the risk and diagnosis of CAD.

Premenopausal women have a lower incidence of CAD, and women present with symptomatic CAD 10 years later than men.²⁵ Although premenopausal women have a lower incidence of CAD, in postmenopausal women, complication rates after an acute MI are greater than in men, possibly as a result of associated comorbidities. Phase II of the Thrombolysis in Myocardial Infarction trial compared the incidence of recurrent infarctions and deaths for women and men after acute MI.²⁶ The 6-week reinfarction and mortality rate was found to be significantly higher for women than for men. After a 1-year follow-up, the mortality rate among men and women was 6.5% and 11.1%, respectively. The risk factors associated with a higher incidence of reinfarction and death in women were age (with women presenting at a significantly older age than men), congestive heart failure (CHF), systemic hypertension, and the presence of diabetes mellitus.

Congestive Heart Failure

A history of CHF is positive if any of the following are present: a previous history of CHF, pulmonary edema, dyspnea on exertion or paroxysmal nocturnal dyspnea, bilateral rales or an S₃ gallop on physical examination, or a chest x-ray suggestive of pulmonary vascular redistribution. These are all considered to be independent predictors of cardiac risk.¹¹ CHF is known to be associated with a poorer outcome in patients undergoing noncardiac surgery.^{23,24} Therefore, every effort should be made to identify unsuspected CHF and its

probable cause and initiate treatment if possible. Preoperative assessment of left ventricular function by an echocardiogram can determine the severity of ventricular dysfunction and aid in perioperative management.

Valvular Heart Disease

Cardiac murmurs are frequently present in patients preparing to undergo noncardiac surgery. Severe, symptomatic aortic stenosis is a relative contraindication to elective noncardiac surgery and necessitates an aortic valve replacement prior to all other surgical interventions.^{23,27,28} In patients with severe aortic stenosis who are unwilling to undergo cardiac surgery or are otherwise not ideal candidates for an aortic valve replacement, noncardiac surgery poses a risk of developing an acute MI and a mortality risk of approximately 10%.^{29–31} In these patients, percutaneous balloon aortic valvuloplasty may be considered to minimize their perioperative risk of noncardiac surgery.^{27,32}

Although rare, mitral stenosis is important to recognize. In mild or moderate cases, ensuring control of heart rate is crucial perioperatively as tachycardia leading to a reduction in diastolic filling can lead to severe pulmonary congestion. Significant mitral stenosis increases the risk of CHF. However, unlike in the case of aortic stenosis, preoperative surgical correction of mitral valve disease is generally not indicated prior to noncardiac surgery except in the most severe cases, when cardiac complications and mortality are inevitable without correction.

When present, aortic regurgitation requires long-term follow-up and appropriate medical treatment to control volume and to reduce afterload. Mitral regurgitation often presents as a result of mitral valve prolapse or following an MI that leads to left ventricular remodeling. In cases of severe mitral regurgitation, afterload reduction with the use of diuretics provides maximal benefit in terms of hemodynamic stabilization before high-risk surgery. Perioperative antibiotic and anticoagulation prophylaxis is also recommended for patients with mitral valve regurgitation and those patients with a prosthetic valve to guard against bacteremia and the need for anticoagulation.⁶ For patients undergoing minimally invasive procedures, the American College of Chest Physicians Consensus Conference on Antithrombotic and Thrombolytic Therapy recommended briefly titrating the international normalized ratio (INR) to the low or subtherapeutic range and restarting the normal dose of oral anticoagulation immediately postprocedure.³³

Arrhythmias and Conduction Defects

Cardiac arrhythmias and conduction disturbances are also common findings on preoperative evaluation, specifically in the elderly population.²³ Both supraventricular and ventricular arrhythmias are known to serve as independent risk factors of cardiac events in the perioperative period; however, asymptomatic ventricular arrhythmias are considered harmless.^{23,34} Regardless, any arrhythmia must warrant a search for underlying causes, such as cardiopulmonary disease, silent myocardial ischemia or infarction, drug toxicity, or metabolic derangements.

Most often cardiac arrhythmias indicate an underlying cardiac problem. Atrial fibrillation is the most common type of supraventricular tachycardia encountered in elderly

patients. Atrial fibrillation or supraventricular arrhythmias can lead to ischemia by increasing myocardial oxygen demand in patients with CAD and may produce life-threatening ventricular fibrillation. Single, premature ventricular contractions, ventricular ectopy, and nonsustained ventricular tachycardia are not associated with an increased risk of nonfatal MI or cardiac death in the perioperative period and do not necessitate therapy unless the patient is hemodynamically compromised.^{34,35} Nevertheless, patients experiencing either sustained or nonsustained ventricular tachycardia perioperatively should be referred to a cardiologist for evaluation of their ventricular function and be screened for CAD. A patient found to have a complete atrioventricular block, which can increase operative risk, may require temporary or permanent transvenous pacing.

Implanted Pacemakers and Implantable Cardiac Defibrillators

Each year, more than 500,000 patients undergo placement of either a permanent pacemaker or an implantable cardiac defibrillator (ICD). The presence of a pacemaker or an ICD has a significant impact on preoperative, intraoperative, and postoperative patient management because of the potential for adverse interactions between electrical or magnetic activity and pacemaker or ICD function. These undue interactions occur as a result of the electrical current generated by use of electrocautery or cardioversion, use of antiarrhythmic agents, and anesthetic agents on pacing and sensing thresholds. Patients with ICDs and pacemakers must be recognized prior to surgery so that the correct records can be obtained that identify the type of device. Patients who are pacemaker dependent must have their device evaluated within 3 to 6 months before and after any major surgical procedures, particularly when the surgery involves large amounts of electrocautery. During surgery, the device should be inactivated and the patient should have both continuous ECG monitoring and continuous pulse oximetry monitoring to identify any life-threatening arrhythmias. In the event that an emergency cardioversion is required, the paddles must be placed away from the implanted device. Following surgery, the device should be reactivated and its function should be reassessed.

Cardiomyopathy

In patients with cardiomyopathy undergoing noncardiac surgery, preoperative recommendations should be made after a detailed understanding of the pathophysiology causing the cardiomyopathy. Understanding the primary cause is crucial to intraoperative and postoperative management of intravenous fluids. In the presence of signs and symptoms of heart failure, preoperative assessment of left ventricular function by an echocardiogram can determine the severity of systolic and diastolic dysfunction and help guide perioperative management.

In hypertrophic obstructive cardiomyopathy, a reduction in blood volume combined with a lower systemic vascular resistance and higher venous capacitance leads to outflow obstruction. The reduced filling pressures of the heart can cause a decrease in stroke volume with a risk of developing hypotension, arrhythmias, and heart failure. Major surgery and an increased duration of surgery were identified as independent risk factors for adverse cardiac outcomes in patients with cardiomyopathy.^{36,37}

Hypertension

Stage 1 (systolic blood pressure < 160 mm Hg and diastolic blood pressure < 100 mm Hg) and stage 2 (systolic blood pressure ≥ 160 mm Hg and diastolic blood pressure ≥ 100 mm Hg) hypertension are not independent risk factors for perioperative cardiovascular complications [see Table 3].³⁸ However, hypertension is a useful marker for potential CAD, with treatment of CAD reducing death as a result of stroke and CHF.³⁹ Intraoperative blood pressure fluctuations correlate with ECG changes suggestive of myocardial ischemia in patients; therefore, control of blood pressure preoperatively can lower the risk of perioperative ischemia.

A physical examination and a few basic laboratory tests can help detect important causes of hypertension. If there is a suspicion for pheochromocytoma, surgery should be delayed to permit its exclusion. A delay in the radial to femoral artery pulse suggests coarctation of the aorta, whereas a loud abdominal bruit may imply renal artery stenosis, and hypokalemia in the absence of diuretic therapy indicates the possibility of hyperaldosteronism.

If the preliminary evaluation determines hypertension to be mild or moderate, there is no evidence to suggest that it is beneficial to delay surgery. However, effective preoperative blood pressure control is beneficial, and antihypertensive medications should be continued. Care should be taken to avoid withdrawal of beta blockers and clonidine because of potential rebound changes in heart rate and blood pressure.

For stage 3 hypertension (systolic blood pressure ≥ 180 mm Hg and diastolic blood pressure ≥ 110 mm Hg), the possible risk of delaying surgery needs to be weighed against the benefit. Blood pressure can usually be lowered within a matter of several hours with rapidly acting intravenous agents if needed; however, there are no clear data favoring one type of medication.⁴⁰ Beta blockers are the predominant agents for the treatment of preoperative hypertension. Preoperative administration of beta blockers decreases the incidence of postoperative atrial fibrillation, and in patients who have or are at risk for CAD, treatment with beta blockers during hospitalization can reduce mortality and the incidence of cardiovascular complications.^{41,42} Finally, patients with preoperative hypertension are more likely to develop

Table 3 Classification of Hypertension

Stage	Systolic BP (mm Hg)	Diastolic BP (mm Hg)
Normal	< 120	< 80
Prehypertension	120–139	80–89
Stage 1	140–159	90–99
Stage 2	≥ 160	≥ 100
Stage 3	≥ 180	≥ 110
Isolated systolic	≥ 140	< 90
Isolated diastolic	< 140	≥ 90

Based on the 2007 guidelines for the management of arterial hypertension: the Task Force for the Management of Arterial Hypertension of the European Society of Hypertension (ESH) and of the European Society of Cardiology (ESC).³⁸
BP = blood pressure.

intraoperative hypotension than their normotensive counterparts, which is seen predominantly in patients who are on angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor antagonists, which may be attributable to a decrease in vascular volume.⁴³ Therefore, blood pressure should be closely monitored intraoperatively and patients should be resuscitated as needed.

PROCEDURE-RELATED RISK FACTORS

Preoperative cardiac evaluation can reliably predict postoperative cardiac outcomes to a reasonable extent and may alter the surgical decision-making process through interventions that reduce both perioperative risk and long-term mortality. Interventions must be made with the anticipation that the patient will live long enough to benefit from the elective surgery to prevent long-term mortality. Different cardiac risks are associated with each operation. The surgery-specific factors can be classified as low, intermediate, or high depending on the urgency, stress levels, duration of procedure, fluid shifts, episodes of hypotension, and blood loss [see Table 4].⁷ Short procedures in general are associated with minimal fluid shifts and minimal blood loss, whereas procedures requiring longer operative times are associated with large fluid shifts, higher risks of blood loss, and hypotension and pose greater risk of postoperative myocardial ischemia and respiratory depression.

Cardiac complications and mortality rates are more likely to occur with emergency surgical procedures than with elective operations as the need for immediate surgical interventions does not allow for optimal preoperative evaluation and management.⁴⁴ The mortality rate for elective repair of an asymptomatic abdominal aortic aneurysm is considerably lower (3.5%) than that for a ruptured aneurysm (42%).⁴⁵ For

elective surgery, cardiac risk depends on a number of factors, including the magnitude of the surgical procedure. The morbidity and mortality rates are low in superficial procedures performed in an outpatient setting.⁴⁶

Perioperative cardiac complications are common causes of morbidity and mortality in the surgical population. A complete preoperative assessment can identify risk factors, which can then be modified to minimize the risk of these complications occurring.

Pulmonary Risk Assessment

Assessment of perioperative risk has generally focused on minimizing cardiac complications, but pulmonary complications are found to be just as common in surgical patients. In a study of 3,970 patients undergoing noncardiac surgery, rates of pulmonary complications such as respiratory failure and pneumonia were found to be higher than pulmonary edema and MI, the most common cardiovascular complications.⁴⁷ Pulmonary complications range from minor complications such as atelectasis to more severe episodes of pneumonia and respiratory failure requiring mechanical ventilation. Depending on the severity of the postoperative pulmonary complication, the length of a hospital stay can be prolonged by up to 2 weeks.^{48,49} A study of the National Surgical Quality Improvement Program (NSQIP) found postoperative pulmonary complications to be the most costly complications, more so than cardiac, infectious, and thromboembolic events.⁵⁰

The risk of postoperative pulmonary complications depends on both patient factors such as smoking, a history of COPD, asthma, and obstructive sleep apnea and procedure-related risk factors.

PREOPERATIVE EVALUATION

History

A thorough history of the patient's past and present symptoms and clinical findings are extremely important in evaluating surgical patients for potential postoperative pulmonary complications. Care should be taken to obtain and evaluate for symptoms such as exercise intolerance, cough, and unexplained dyspnea that may indicate potential lung pathology. The Arozullah respiratory failure index is a promising tool for pulmonary risk assessment [see Table 5].⁵¹ In this classification scheme, the type of surgery, urgency of the surgery, serum albumin less than 3.0 g/dL, blood urea nitrogen (BUN) greater than 30 mg/dL, functional status of the patient, history of COPD, and age are awarded different points. Patients with 10 or fewer points have an associated 0.5% risk of respiratory failure, whereas those with more than 40 points have over 26% risk of respiratory failure.

Physical Examination

Signs of decreased breath sounds, wheezes, rhonchi, or prolonged expiratory phase will indicate underlying pulmonary disease.⁵² Patients with COPD can present with the symptoms of either emphysema or chronic bronchitis. Those with emphysema will have a barrel chest, increased respiratory rate, and use of accessory muscles of breathing, giving them the name "pink puffers." Patients with classic chronic bronchitis will present with signs of cyanosis, such as pursed blue lips, giving them the name "blue bloaters."

Table 4 Selected Surgical Procedures Stratified by Degree of Cardiac Risk

Degree of Cardiac Risk	Type of Procedure
Low (< 1%)	Endoscopic Ambulatory Ophthalmic Aesthetic Reconstructive Endocrine Gynecologic Breast Dental
Low intermediate (1–5%)	Minor vascular procedures (carotid endarterectomy) Abdominal Thoracic Neurosurgical Otolaryngologic
High intermediate (1–5%)	Orthopedic Urologic
High (> 5%)	Emergency Major vascular Extensive surgical procedures with profound estimated blood loss, large fluid shifts, or both Unstable hemodynamic situations

Table 5 Arozullah Respiratory Failure Index to Assess Preoperative Pulmonary Risk

Preoperative Predictor of Pulmonary Complication		Points Assigned
Abdominal aortic aneurysm		27
Thoracic procedure		21
Neurosurgery; upper abdominal, peripheral vascular procedure		14
Neck procedure		11
Emergency surgery		11
Albumin < 3.0 g/dL		9
BUN > 30 mg/dL		8
Suboptimal functional status		7
COPD		6
Age > 70 yr		6
Age 60–69 yr		4
Class	Cumulative Points	Predicted Respiratory Failure (%)
1	≤ 10	0.5
2	11–19	1.8
3	20–27	4.2
4	28–40	10.1
5	> 40	26.6

BUN = blood urea nitrogen; COPD = chronic obstructive pulmonary disease.

Based on the medical history and patient-specific variables, a preset point system is applied first. The cumulative point system is applied next to assess preoperative pulmonary risk.

Pulmonary Function Tests

Only patients who are scheduled for lung resection need to have preoperative pulmonary function tests performed. For the remaining procedures, the 2006 American College of Physicians guideline advocates against routine use of preoperative spirometry to estimate the risk of postoperative pulmonary complications.⁵³ However, for patients with unexplained dyspnea or exercise intolerance and those with COPD and poorly controlled asthma, pulmonary function tests should be ordered to determine disease severity as these patients will benefit from more aggressive preoperative management.⁵³

In addition to pulmonary function tests, a chest x-ray should be obtained in patients undergoing high-risk surgery who are over age 50 years or if cardiac or pulmonary disease is suggested by the clinical evaluation, unless one has been obtained in the past 6 months.⁵⁴

PATIENT-RELATED RISK FACTORS

Age and General Health Status

The role of age as an independent predictor of postoperative pulmonary complications is unclear. Although several

studies have suggested a higher risk of pulmonary complications with advanced age, the data were unadjusted for the patients' overall health status.⁵⁵ Using multivariate analysis and adjusting for age-related comorbidities, a more recent systematic review estimated that even otherwise healthy older patients carry a substantial risk of pulmonary complications after surgery.⁵⁶ As a result of the controversy regarding age as a risk factor, many physicians use the American Society of Anesthesiologists (ASA) score to assess the risk of complications as it is based on a patient's overall health status [see Table 6].

Smoking

Smoking is one of the most important independent predictors of postoperative pulmonary complications. Several studies since the 1980s have confirmed that cigarette smoking increases the risk of postoperative pulmonary complications.^{57–59} One study reported an odds ratio of 5.5 for increased risk of pulmonary complications following elective surgery in smokers compared with nonsmokers.⁵⁷ In another study, patients who had stopped smoking for less than 2 months had four times as many pulmonary complications as those who had quit smoking for more than 2 months.⁵⁸ To minimize pulmonary complications, patients should be instructed to quit smoking for at least 8 weeks prior to surgery.

Chronic Obstructive Pulmonary Disease

Patients with severe COPD can have up to a sixfold greater risk of developing a postoperative pulmonary complication than patients without the disease.^{60,61} Findings of COPD on a physical examination, such as decreased breath sounds, prolonged expiration, rales, wheezes, or rhonchi, correlate with a higher risk of postoperative complications.⁴⁹ In patients with pulmonary dysfunction, the risk-to-benefit ratio should be considered in making the ultimate decision regarding surgical intervention.

Asthma

It was initially believed that a history of asthma contributed to postoperative pulmonary complications, but studies have demonstrated that patients with well-controlled asthma do not have a higher than average surgical risk. One such study

Table 6 American Society of Anesthesiologists Score: Patient's Overall Health and Ability to Undergo Surgery

Class	Physical Status
1	Healthy patient with no systemic disease, not at any extreme of age
2	Patient with one-system, well-controlled disease not affecting daily activity
3	Patient with multisystem disease that limits daily activity
4	Patient with severe disease that is poorly controlled or end stage
5	Patient who is not expected to survive without an operation
6	Patient whose organs are being removed for donation

reported no major pulmonary complications and 14 minor complications, including bronchospasm and laryngospasm, in 706 asthma patients undergoing general surgery.⁶² In contrast, those with uncontrolled asthma, considered those patients with recent inhaler use or a visit to the emergency department, had a significantly higher incidence of pulmonary complications. Therefore, it is imperative to ask about recent medication use, particularly the need for rescue inhalers, and a course of systemic corticosteroids may be necessary to optimize the patient's pulmonary function.

Obstructive Sleep Apnea

Obstructive sleep apnea is an emerging risk factor for postoperative pulmonary complications. Pulmonary complications such as pneumonia and unplanned reintubation attributable to obstructive sleep apnea have only recently been appreciated.⁶³ The need to screen for obstructive sleep apnea prior to elective surgery is currently being investigated.

Obesity

Morbid obesity is associated with physiologic changes including reduction in lung volumes, ventilation/perfusion mismatch, and relative hypoxemia. Whereas earlier studies found neither obesity nor body mass index (BMI) to be an absolute risk factor for postoperative pulmonary complications, more recent prospective studies have found obesity (defined as BMI > 27 kg/m²) to be one of six independent risk factors for postoperative pulmonary complications.^{52,64,65} In another prospective study of 1,000 patients who underwent laparotomy, obesity (defined by BMI > 25 kg/m²) was found to be an independent risk factor for postoperative pulmonary complications. The inconsistencies found in these reports may be attributable to a difference in study design or failure of the authors to differentiate obesity from other comorbid conditions. A recent systematic review found that only one of eight studies using multivariate analysis identified obesity as an independent predictor of pulmonary complications postoperatively.⁵⁶ Hence, obesity is not considered a major risk factor for postoperative pulmonary complications and, therefore, should not affect surgical management of a given patient.

Pulmonary Hypertension

Even mild to moderate pulmonary hypertension predisposes surgical patients to higher postoperative complications such as cardiac dysrhythmias, congestive heart failure, renal insufficiency, and sepsis. Risk is greater in emergency procedures, major procedures, and those of extended duration and is irrespective of the etiology of pulmonary hypertension.⁶⁶ Pulmonary hypertension has been found to be an important predictor of adverse cardiopulmonary complications and is associated with higher rates of mortality and major morbidity.⁶⁷ Therefore, care should be taken while considering surgery and its potential risks in these patients, with efforts made to optimize medical management with supplemental oxygen, diuretics, vasodilators, and other appropriate medications.

Heart Failure

As per the systematic review that formed the foundation of the American College of Physicians guideline, the risk of

postoperative pulmonary complications appears higher in patients with heart failure than with COPD.⁵⁶ The collective adjusted odds ratio in this study for pulmonary complications was 2.93 (95% CI 1.02 to 8.43) for heart failure patients versus 2.36 (1.90 to 2.93) for patients with COPD. Therefore, a thorough perioperative assessment of clinical status and risk-to-benefit ratio should be performed while considering surgery in these patients.

PROCEDURE-RELATED RISK FACTORS

The surgical site is the single most important factor in predicting the overall risk of postoperative pulmonary complications. One of the factors responsible for postoperative pulmonary complications is a reduction in lung volume, which is a common occurrence after thoracic and upper abdominal surgery attributable to a reduced tidal volume, loss of sighing breaths, and an increased respiratory rate.⁶⁸ Diaphragmatic dysfunction, postoperative pain, and splinting also play a significant role in this aspect. Furthermore, the residual effects of anesthesia and use of postoperative opioids also lower a patient's respiratory drive, leading to inhibition of the cough response and impaired mucociliary clearance, which predisposes to the risk of postoperative infection.⁶⁹ A decrease in functional residual capacity increases the risk of atelectasis, pneumonia, and ventilation/perfusion mismatch, resulting in impaired gas exchange and postoperative hypoxemia.⁷⁰

In one systematic review, complication rates for upper abdominal surgery were found to be higher than those for lower abdominal surgery, most probably attributable to the effect of the incision on respiratory muscle and diaphragmatic function.⁵⁶ On the other hand, procedures such as laparoscopic cholecystectomy were associated with quicker recovery times, reduced pain, and lower reduction in lung volumes postoperatively.⁵⁶

Surgical procedures longer than 3 to 4 hours are also associated with a higher risk of pulmonary complications.^{52,71,72} Therefore, if possible, the length of the procedure should be considered when assessing the risk of surgery to its benefit in a high-risk patient.

It is yet to be determined if pulmonary risk of spinal or epidural anesthesia varies when compared with that of general anesthesia. The largest systematic review assessing this risk factor examined the results of 141 trials including 9,559 patients.⁷³ According to this study, there was a reduction in the incidence of pneumonia and respiratory depression among patients who received either epidural or spinal anesthesia with or without general anesthesia versus those who received general anesthesia alone.⁷³ It is likely that general anesthesia is associated with a higher risk of clinically important pulmonary complications than epidural or spinal anesthesia; hence, regional nerve block should be considered when possible for high-risk patients to minimize postoperative complications. Finally, the long-acting neuromuscular blocker pancuronium is also associated with a higher incidence of postoperative pulmonary complications than shorter-acting agents because of its residual neuromuscular blockade, leading to a higher incidence of postoperative pulmonary complications.⁷⁴

Perioperative pulmonary complications are recognized as a significant cause of morbidity and mortality, necessitating reintubation, prolonging hospital stay, and increasing health

care costs. By addressing the patient's pulmonary risk factors and the risks of the surgery to be undertaken, the physician performing the preoperative evaluation can decrease these complications.

Renal Risk Assessment

Mild to moderate renal impairment is often asymptomatic, with an incidental finding of elevated creatinine during preoperative evaluation. On the contrary, patients with severe renal failure often require dialysis treatment and eventual kidney transplantation. Renal failure can lead to many complications, including arrhythmias as a result of elevated potassium levels, shortness of breath as a result of pulmonary edema, and anemia. In patients undergoing surgery, these complications may worsen and become life-threatening. Renal insufficiency is also an independent risk factor for postoperative complications and requires dosage adjustments of anesthetics and other medications with potential nephrotoxic effects.¹¹

PREOPERATIVE EVALUATION

History

Although most patients with mild renal failure may not exhibit any symptoms, a detailed history may elucidate symptoms in patients who are unaware of having renal impairment. For instance, anemia, as a result of a decrease in erythropoietin production, may cause fatigue. Patients may also note an increase in lower extremity swelling, weight gain, or shortness of breath attributable to increased fluid.

Physical Examination

On physical examination, a physician may notice that a patient has an increased respiratory rate while attempting to eliminate carbon dioxide to compensate for metabolic acidosis. On lung examination, crackles can be heard in patients with pulmonary edema. Fluid overload will also cause generalized edema, which is most prominent in dependent areas, most commonly the lower extremities.

Laboratory Testing

All patients in whom there is a suspicion of renal impairment should undergo laboratory testing, to include the BUN level and serum creatinine. Likewise, these baseline tests should be ordered for patients who may be exposed to hypotension during the procedure or to nephrotoxic agents, such as contrast media used for computed tomographic (CT) scans, as this is a common cause of acute renal injury. In the setting of preexisting renal disease, a reduced glomerular filtration and/or a preoperative creatinine level greater than 2 mg/dL predisposes patients to postoperative renal dysfunction requiring dialysis and increases their long-term morbidity and mortality compared with patients without renal disease.⁷⁵⁻⁷⁷ Creatinine clearance is an additional marker to assess renal function and predict postoperative complications, determined from the serum creatinine concentration and the patient's age and weight. The creatinine clearance provides a more accurate assessment of renal function than serum creatinine alone.^{78,79} Once an elevated creatinine or creatinine clearance has been discovered, further workup can be done to assess the cause of the patient's renal impairment.

Analysis of the urine is a simple and cost-effective way to detect unsuspected renal disease and/or urinary tract infections. The detection of proteins on urinalysis indicates that the renal glomeruli are injured and are allowing large molecules to filter through into the urine. The presence of urinary casts can be associated with renal conditions such as acute interstitial nephritis, glomerulonephritis, and acute tubular necrosis. Urine sodium and creatinine, if included in the analysis of the urine, can be used to calculate the fractional excretion of sodium (FeNa) and aid the physician in distinguishing prerenal from postrenal causes of renal failure [see Table 7]. Urinary tract infections can also be detected with urinalysis by the presence of increased nitrites and white blood cells. Detection of a urinary tract infection preoperatively is important as it has the potential to cause bacteremia and postsurgical wound infections, particularly with prosthetic surgery.⁸⁰ Patients with positive urinalysis and urine culture can be treated with antibiotics and then taken into surgery without delay. Nonetheless, whether a positive urinary finding with consequent antibiotic treatment prevents postsurgical infections is uncertain as the findings in the literature have been contradictory.^{81,82} A cost-effective analysis established that for most types of clean-wound surgery, a routine preoperative urinalysis is not cost-effective.⁸³ Hence, routine urinalysis does not need to be ordered preoperatively for most surgical procedures, except in the setting of suspected urinary tract infections.

PATIENT-RELATED RISK FACTORS

Dialysis Patients

Patients on long-term dialysis have chronic renal dysfunction that places them at an increased risk for postoperative morbidity and mortality. Much of this increased risk is attributable to associated comorbidities such as CAD and hypertension, which necessitates appropriate cardiac preoperative evaluation. As a result of their dependence on dialysis, these patients may also experience electrolyte abnormalities, most commonly hyperkalemia, as well as fluid overload, which may lead to complications such as pulmonary edema and respiratory failure. All dialysis patients scheduled to undergo surgery must undergo a routine history and physical examination as well as baseline laboratory testing not only to evaluate their level of renal dysfunction but also to identify other potential risk factors for morbidity, such as anemia and poor nutritional status. In patients undergoing elective surgery, preoperative dialysis should optimize a patient's fluid and electrolyte levels. In the event of emergency surgery, dialysis is usually unable to be performed prior to operative

Table 7 Assessment of Renal Failure

FeNa (%)	Cause of Failure
< 1	Prerenal
> 1	Intrinsic
> 4	Postrenal

FeNa = $100 \times (\text{Urine sodium} \times \text{plasma creatinine}) / (\text{Plasma sodium} \times \text{urine creatinine})$
Fractional excretion of sodium (FeNa) is the percentage of sodium that is filtered by the kidney and excreted in the urine. It is most commonly used to assess the cause of acute renal failure.

intervention. In this instance, hyperkalemia is the most common and serious electrolyte abnormality that should be evaluated. This evaluation should include an ECG to rule out cardiac abnormalities attributable to the elevated potassium, as evidenced by peaked T waves. If the patient is stable, with no ECG changes and a potassium level less than 6.2 mEq/L, he or she should be able to undergo emergency surgery with careful intraoperative monitoring.⁸⁴ In the event that ECG changes are present and surgery must be undertaken, medical management in the form of calcium gluconate and insulin with D50W should be performed. In all dialysis-dependent patients undergoing surgery, arrangements should be made to provide for continued dialysis treatment during the patient's hospitalization.

Hepatic Risk Assessment

Patients with hepatic dysfunction are at increased risk for multiple complications after elective surgery. Depending on the severity of their liver disease, they may have a coagulopathy that puts them at increased risk for bleeding or an underlying hepatorenal syndrome that increases the risk of postoperative renal failure.

In certain settings, the risks of the above complications and the mortality rate are unacceptably high, so elective surgery is contraindicated. In patients with fulminant hepatitis, acute liver failure, and acute alcoholic hepatitis, early studies have reported mortality rates of 10 to 58%, making these conditions absolute contraindications to elective surgery.^{85,86}

In patients without the above conditions, the risk of perioperative complications increases with the increasing severity of liver disease. Two scoring systems have been widely used by physicians to assess the severity of liver disease, the Child-Pugh scoring system and the Model for End-Stage Liver Disease (MELD) score [see Table 8 and Table 9]. The

Table 8 Child-Pugh Score to Predict Mortality of Cirrhotic Patients and the Need for Liver Transplantation

Variables	Points		
	1	2	3
Total bilirubin (mg/dL)	< 2	2–3	> 3
Albumin (g/L)	> 3.5	2.8–3.5	< 2.8
INR	< 1.7	1.7–2.3	> 2.3
Ascites	None	Mild (controlled with diuretics)	Severe
Encephalopathy	None	Stage I or II	Stage III or IV
Class	Points		
A	5–6		
B	7–9		
C	10–15		

INR = international normalized ratio.

Table 9 Model for End-Stage Liver Disease (MELD)

$$\text{MELD} = 3.78 [\ln \text{ total bilirubin (mg/dL)}] + 11.2 [\ln \text{ INR}] + 9.57 [\ln \text{ serum creatinine (mg/dL)}] + 6.43$$

INR = international normalized ratio; ln = natural log.

The MELD score is used to assess the severity of liver disease and prioritizes patients awaiting liver transplantation.

Child-Pugh scoring system was initially developed in the 1970s and was the standard for assessing morbidity and mortality in cirrhotic patients until the development of the MELD score. The MELD score was created to predict mortality after transjugular intrahepatic portocaval shunt (TIPS) placement but is now used to prioritize patients awaiting liver transplantation and as a predictive model of perioperative mortality. A 2010 study in patients undergoing abdominal surgery showed mortality rates of 2% in Child-Pugh class A patients and rates of 12% for both class B and C.⁸⁷ Because of this and various other studies, elective surgery is contraindicated in Child-Pugh class C cirrhotics.⁸⁸ The MELD score has also been shown to predict morbidity in patients undergoing cholecystectomy, hepatectomy, and cardiac surgery in numerous studies.^{89–91} It has been recommended that patients with a MELD score greater than 15 not undergo elective surgery as the risk of a complication outweighs any surgical benefit.⁹² Although both scoring systems are in use, numerous studies have demonstrated the MELD score to be superior to the Child-Pugh score in predicting perioperative morbidity and mortality.^{93,94}

PREOPERATIVE EVALUATION

History

The history of a patient with hepatic dysfunction is useful to identify not only patients in whom the risk of elective surgery would outweigh the benefits but also those with mild disease in whom medical management may be optimized to minimize those risks. A thorough history can identify worsening encephalopathy and spur treatment of increasing ammonia levels with lactulose. In an alcoholic cirrhotic patient, a complete history helps not only in assessing liver dysfunction but also in determining whether the patient continues to abuse alcohol. Surgical patients with alcohol abuse are not only at risk for withdrawal during their hospitalization but also have higher rates of postoperative hemorrhage, cardiac complications, and sepsis.⁹⁵

Physical Examination

The physical examination can identify patients with ascites, who may benefit from preoperative diuretic therapy or paracentesis to minimize the occurrence of wound complications. Physicians who perform complete examinations may also discover patients with previously undiagnosed hepatic dysfunction as a result of the presence of jaundice, which should then prompt further laboratory assessment.

Laboratory Evaluation

All patients with suspected or known hepatic dysfunction should have an assessment of their liver function. This should include a total bilirubin level, which can then be used to calculate a Child-Pugh or MELD score. This evaluation

should also include a measurement of the patient's INR. This is helpful not only in calculating a risk score but also in identifying patients at an increased risk for bleeding in whom treatment with vitamin K and/or fresh frozen plasma can be initiated to decrease their coagulopathy. Evaluation of renal function should also be performed in an initial assessment of a cirrhotic patient and should include a creatinine level to both calculate risk scores and identify patients at increased risk for developing acute renal failure. Small studies have demonstrated improvements in renal function in patients given a combination of midodrine, an α_1 -adrenergic agonist, and octreotide, a somatostatin analogue, as well as terlipressin, a vasopressin analogue, combined with albumin, but larger trials are yet to be done.^{96,97} In patients who do develop acute renal failure after surgery, dialysis may need to be initiated, and a surgeon should not hesitate to do so as the mortality of a patient in liver failure with hepatorenal syndrome is significantly worse than in a patient with adequate renal function.⁹⁸

All patients with liver disease risk hepatic decompensation with surgery; therefore, identifying these patients prior to surgical intervention can not only minimize the risk of complications but also can prepare the surgeon and the patient for such a possibility.

Hematologic Risk Assessment

The hematologic risk assessment should include an evaluation of conditions that can increase perioperative bleeding, as well as those that place the patient at an increased risk for the development of clots. The preoperative assessment of a patient's hematologic risk should take into consideration patient factors such as history, physical examination, and laboratory tests, as well as procedural risks.

PREOPERATIVE EVALUATION

History

A thorough history should include questions concerning easy bruising and prolonged bleeding, a previous need for blood transfusions, and the use of anticoagulants or antiplatelet drugs. This evaluation should also include questions regarding a history of blood clots and conditions that can increase hypercoagulability, such as malignancies, oral contraceptive use, and smoking.

Physical Examination

On physical examination, patients with bleeding disorders may display numerous petechiae and ecchymoses or bleeding mucosa suggestive of platelet dysfunction or deficiency. Deformed joints or bleeding into joints points to a diagnosis of hemophilia, which needs to be treated appropriately prior to surgery. Patients with a deep vein thrombosis may have a swollen and painful extremity on examination.

Laboratory Evaluation

In evaluating patients at risk for excess bleeding during surgery, prothrombin time (PT), partial thromboplastin time (PTT), and bleeding time should be performed. When done routinely, abnormalities in these tests are not clear indicators of the risk of perioperative hemorrhage.^{10,99–101} The finding of an abnormal PT in an otherwise normal patient does not

change patient management or modify the likelihood of a complication.³⁰ Therefore, the current ACC/AHA guidelines advise against routine preoperative measurement of hemostasis and recommend testing only patients with an existing bleeding disorder or an illness associated with an abnormal bleeding tendency.¹

PATIENT-RELATED RISK FACTORS

Hemophilia

Historically, hemophiliacs undergoing surgical procedures faced mortality rates up to 66%, but with the perioperative administration of coagulation factors, mortality has been significantly reduced.^{102,103} In hemophilia type A, with a deficiency in factor VIII, patients should have 100% of their factor levels replenished. Given that hemophilia type B (Christmas disease), attributable to a deficiency in factor IX, is not as severe as type A, it is recommended that 50% of factor levels be administered preoperatively.

Anemia

Anemia puts a strain on the cardiovascular system and a hematocrit less than 28% puts patients at a higher risk for perioperative ischemia and postoperative complications.^{104–106} In the Veterans Affairs NSQIP database, mild preoperative anemia or polycythemia led to an increase in cardiac events and mortality within the 30-day postoperative period in older, primarily male patients who underwent major noncardiac surgery.⁹⁹ Therefore, judicious use of preoperative transfusion in patients with advanced CAD or CHF may be beneficial in reducing perioperative cardiac morbidity.

Hypercoagulability

Factor V Leiden deficiency is the most common congenital cause of spontaneous venous thrombosis. Polycythemia vera, protein C or S deficiency, and antiphospholipid antibody syndrome also lead to an increased risk of thromboembolism in the postoperative period. Many of these patients will require heparin or warfarin therapy postoperatively.

PROCEDURE-RELATED RISK FACTORS

The type of surgery to be performed should also be considered when deciding whether a patient is at an increased risk for bleeding. Low-risk surgeries are those in which a limited amount of dissection takes place, no vital organs are involved, and the surgical site is exposed, allowing for direct hemostasis. An inguinal hernia repair would be considered low-risk surgery. On the contrary, exploratory laparotomies and thoracotomies are referred to as high-risk surgeries because they involve manipulation of vital organs and extensive dissection. In these cases, a thorough history and physical and laboratory testing should be performed to rule out disorders that could increase the risk of bleeding complications.

Preoperative Medication Management

One of the most important aspects of the preoperative evaluation is a review of the patient's medication history. A physician must know not only when to discontinue medications because of their potential surgical and anesthetic complications but also when to continue them to avoid the adverse effects of withdrawal and when to substitute medications

when their absorption may be decreased in the immediate postoperative period.

Close consideration should be given to any cardiovascular medications the patient is taking on a regular basis as abrupt discontinuation can compromise an otherwise hemodynamically stable patient [see Table 10]. Beta blockers are one of the most beneficial medications for patients to continue taking in the perioperative period. Beta blockers reduce ischemia by decreasing myocardial oxygen demand and may also prevent arrhythmias when taken perioperatively. ACE inhibitors and angiotensin II receptor blockers reduce blood pressure via the renin-angiotensin system. For patients with hypertension, these agents are continued unless the patient is hemodynamically unstable or there is a concern for renal insufficiency.¹⁰⁷ Alpha₂ agonists, such as clonidine, are centrally acting sympatholytic drugs that have also been shown to improve perioperative outcomes, and abrupt withdrawal can cause rebound hypertension; hence, these medications should be continued.^{108,109} In patients undergoing noncardiac surgery, the use of calcium channel blockers was found to reduce the incidence of ischemia and atrial arrhythmia, leading to the recommendation to continue these medications perioperatively.¹¹⁰ There is also evidence that perioperative fluvastatin, an HMG-CoA reductase inhibitor, improves postoperative cardiac outcomes and should be continued the day of surgery.¹¹¹

Diuretics can cause hypovolemia and significant hypotension in surgical patients and should not be taken the morning of surgery.¹¹² Other drugs to discontinue are the nonstatin hypolipidemic agents and fibric acid derivatives. These agents can cause myopathy and rhabdomyolysis, particularly when used in combination with a statin. Bile sequestrants such as

cholestyramine and colestipol should also be discontinued as they can interfere with the absorption of several medications given postoperatively.¹¹³

Many prescription and over-the-counter medications can increase the risk of bleeding postoperatively [see Table 11].¹¹⁴ Antiplatelet agents such as aspirin should be discontinued 7 to 10 days prior to surgery. For those patients whose risk of cardiovascular events is high, but the risk of postoperative hemorrhage is low, aspirin should be continued up to the day of surgery. Warfarin, the most common oral anticoagulant taken by patients, should be discontinued 5 to 7 days prior to surgery. For those patients whose INR remains elevated, fresh frozen plasma can lower the INR to a level acceptable to the operating surgeon.

Diabetic patients taking oral hypoglycemic agents and insulin are another group of patients needing special consideration. Perioperative diabetic management should be geared toward optimizing glycemic control and preventing ketoacidosis. Patients taking oral hypoglycemic agents are advised to withhold their oral medications on the day of surgery and, if necessary, should be treated with subcutaneous short-acting insulin.^{115,116} Likewise, in the postoperative period, if diabetic patients are unable to resume their oral hypoglycemic agents, subcutaneous or intravenous insulin may be required to prevent hyperglycemia. Diabetic patients on insulin therapy should continue their home regimen perioperatively for short procedures. For longer and higher-risk procedures, such as CABG or renal transplantation, intravenous insulin is usually recommended to prevent hyperglycemia and ketosis.^{115,116}

In addition to prescribed medications, many patients scheduled to undergo surgery may be taking herbal medications. These medications may be harmful to the liver, interfere with the coagulation cascade or platelet function,

Table 10 Recommendation for Cardiovascular Agents

Drug	Use	Recommendation for Continuation
ACE inhibitors and angiotensin receptor blockers	Antihypertensive: continuation can result in hypotension if low blood pressure at baseline Heart failure: can lead to hypotension	Continue medication up to and including the day of surgery if using to lower blood pressure. Discontinue on day of surgery if using to treat heart failure and blood pressure is low at baseline. Use IV enalapril postoperatively if needed.
Alpha ₂ agonists	Antihypertensive: abrupt withdrawal can result in hypertension and myocardial ischemia	Continue medication up to and including the day of surgery; switch to transdermal clonidine or IV methyl dopa
Beta blockers	Antihypertensive: abrupt withdrawal can result in hypertension, tachycardia, and myocardial ischemia	Continue medication up to and including the day of surgery; switch to IV propranolol, metoprolol, or labetalol if in a prolonged NPO state
Calcium channel blockers	Antihypertensive: increased risk of bleeding is controversial	Continue therapy up to and including the day of surgery. IV substitution necessary only if unstable hemodynamically (hypertension or arrhythmia).
Diuretics	Heart failure: continuation can lead to hypovolemia and hypotension	Continue medication up to and including the day of surgery but withhold morning dose, if needed give IV postoperatively.
Nonstatin, lipid-lowering agents	Niacin and fibric acid derivatives: rhabdomyolysis. Bile acid sequestrants interfere with absorption of other medications.	Discontinue the day prior to surgery. Can resume with oral intake.
Statins	Lipid-lowering agents: provide cardiovascular protection but may cause myopathy	Continue medication up to and including the day of surgery

ACE = angiotensin-converting enzyme; IV = intravenous; NPO = nihil per os.

Table 11 Recommendation for Antiplatelet Agents and Anticoagulants

Type of Drug	Agent	Effects	Recommendations for Discontinuation
Antiplatelet agents	Aspirin (ASA)	Irreversible platelet inhibitor	7–10 days prior to surgery; those on long-term ASA therapy for coronary/cerebrovascular pathology should continue ASA unless bleeding complications outweigh risk of thrombosis
	Thienopyridines: clopidogrel and ticlopidine	Inhibit platelet aggregation	Clopidogrel 7–10 days prior to surgery Ticlopidine 2 weeks prior to surgery In patients with coronary artery stents, delay elective surgery until patient has completed therapy
	Nonsteroidal antiinflammatory drugs (NSAIDs)	Reversible platelet inhibitor	At least 2 days prior to surgery
	Antiglycoprotein agents: abciximab, tirofiban, eptifibatide	Inhibit platelet aggregation	At least 12 hours prior to surgery
Oral anticoagulants	Warfarin	Inhibition of vitamin K–dependent clotting factors II, VII, IX, X	5–7 days prior to surgery; may need to bridge patient with heparin

Adapted from Backman S et al.¹¹⁴

ASA = acetylsalicylic acid.

Prescription and over-the-counter medications can have antiplatelet and anticoagulant effects, which increase the risk of bleeding perioperatively. Given the reasons for their use, these medications may need to be continued and elective surgery postponed.

Table 12 Recommendation for Herbal Medications

Herbal Medication	Use	Adverse Effect	Recommendation for Discontinuation
Chaparral	Alternative anticancer treatment	Hepatotoxicity	As soon as possible
Coltsfoot	Antitussive and demulcent	Carcinogenic	As soon as possible
Comfrey	General healing agent	Hepatotoxicity	As soon as possible
<i>Ephedra sinica</i>	Noncatecholamine sympathomimetic agent	Cardiac and CNS complications	24 hours prior to surgery
Echinacea	Immunostimulatory effect	Hepatotoxicity; possible allergy	As soon as possible in patients with hepatic dysfunction
Feverfew		Bleeding	At least 7 days prior to surgery
Garlic	Irreversible platelet inhibition	Bleeding	At least 7 days prior to surgery
Germander	Choleretic, antiseptic	Hepatotoxicity	As soon as possible
Ginkgo biloba	Inhibition of platelet-activating factor	Bleeding	At least 36 hours prior to surgery
Ginger	Inhibitor of thromboxane synthase	Bleeding	At least 36 hours prior to surgery
Ginseng	Inhibition of platelet aggregation; antihyperglycemic	Prolonged PT and PTT; hypoglycemia	At least 7 days prior to surgery
Goldenseal		May increase swelling and BP	At least 7 days prior to surgery
Lobelia	Antinausea; expectorant	Respiratory depression, tachycardia, hypotension, coma, death	As soon as possible
Sassafras	Stimulant; antispasmodic	Carcinogenic	As soon as possible
Saw palmetto		May interfere with hormone therapies	At least 7 days prior to surgery
St. John's wort	Inhibits reuptake of serotonin, norepinephrine, and dopamine	May interact with MAOIs	Day of surgery
Valerian	Modulation of GABA neurotransmitter	May potentiate effect of sedative anesthetics	24 hours prior to surgery

Table 12 Continued			
Herbal Medication	Use	Adverse Effect	Recommendation for Discontinuation
Vitamin E		Bleeding	
Yohimbe	Aphrodisiac, sexual stimulant	Hypertension, tachycardia, paralysis, death	As soon as possible

Adapted from Backman S et al.¹¹⁴
BP = blood pressure; CNS = central nervous system; GABA = γ -aminobutyric acid; MAOI = monoamine oxidase inhibitor; PT = prothrombin time; PTT = partial thromboplastin time.
Herbal medications have various adverse effects, and based on the severity of that risk, they should be discontinued accordingly.

or enhance the effects of various anesthetic agents. It is imperative for a physician to be aware of the side effects of certain herbal medications and to advise a patient on when to discontinue their use [see Table 12].¹¹⁴

Conclusion

A complete preoperative evaluation should optimize a patient’s medical status prior to surgical intervention. A thorough history and physical examination supplemented by indicated laboratory testing and studies may uncover

conditions that could lead to unnecessary perioperative complications such as acute MI and renal failure. Although the preoperative evaluation is essential to minimizing complications in surgical patients, it is important to remember that perioperative complications are unavoidable. Therefore, a physician should not only evaluate the patient’s ability to undergo surgery but also anticipate and treat postoperative complications in a timely manner to minimize morbidity and mortality.

32 PERIOPERATIVE ANTITHROMBOTIC THERAPY MANAGEMENT AND VENOUS THROMBOEMBOLISM PROPHYLAXIS

Matthew C. Koopmann, MD, and Herbert Chen, MD, FACS

With expected increases in the elderly patient population requiring surgery, coupled with the overall trend toward increased comorbid conditions in surgical patients, surgeons can expect to encounter more patients receiving preoperative antithrombotic therapy that will need to be managed in the perioperative period. In addition, it can be expected that more patients will come to surgery with risk factors for perioperative venous thromboembolism (VTE) requiring perioperative prophylaxis. Furthermore, various organizations have developed process measure reporting requirements, such as the Centers for Medicare and Medicaid Services (CMS) Physician Quality Reporting Initiative (PQRI),¹ that require surgeons to document appropriate perioperative VTE prophylaxis. Thus, it is imperative that surgeons be able to identify patients at risk for perioperative VTE and provide appropriate and timely prophylaxis.

The management of perioperative anticoagulation and antiplatelet therapy and perioperative VTE prophylaxis is essentially a balancing act between patient risk factors for thrombosis and surgical risk factors for bleeding. The goals of this chapter are to assist the practicing surgeon with

- Identifying patient groups at increased risk for thromboembolism when antithrombotic therapy is interrupted
- Identifying patients for whom bridging anticoagulation should be considered
- Identifying patients who require perioperative VTE prophylaxis
- Identifying patients at increased risk for bleeding complications
- A brief review of the literature and major guidelines regarding perioperative antithrombotic therapy management and perioperative VTE prophylaxis

Perioperative Antithrombotic Therapy Management

The rationale for perioperative bridging anticoagulation for patients receiving long-term warfarin therapy is based on the following assumptions: patients with a therapeutic international normalized ratio (INR) are at increased risk for bleeding during invasive procedures; allowing the INR to fall outside the therapeutic range during the perioperative period exposes patients to an increased risk of thrombotic

complications; bridging anticoagulation (with unfractionated heparin [UFH] or low-molecular-weight heparin [LMWH]) reduces the risk of thrombotic complications in the perioperative period while the INR is subtherapeutic; and the benefit of bridging anticoagulation outweighs the increased risk of post-procedural bleeding. For perioperative bridging anticoagulation to be beneficial, all of these assumptions need to be true for the individual patient.

For most invasive procedures, continuation of oral anticoagulants increases the risk of periprocedural bleeding.² However, there are some procedures for which warfarin may not need to be stopped if there are no additional bleeding risks (e.g., uremia, thrombocytopenia, coagulation factor deficiencies, or recent bleeding complications). These include cataract surgery,³ many dermatologic procedures,⁴ simple dental procedures, and joint and soft tissue aspirations and injections.⁵

For most other elective procedures, warfarin should be stopped for a period prior to the procedure that will allow the INR to fall to an acceptable level on the day of the procedure. For most patients with a steady-state INR between 2 and 3, withholding 4 doses of warfarin (i.e., stopping warfarin 4 days prior to the date of surgery) will allow the INR to fall to less than 1.2 on the day of surgery, with virtually all patients having an INR of 1.5 or less, a level that is safe for most operations except for those in which even minor bleeding can be catastrophic (e.g., intracranial or spine surgery). It may be necessary to stop warfarin sooner (i.e., > 4 doses) if patients have a higher INR (> 3.0) or if they are older as increasing age is a significant independent predictor of smaller decreases in the INR. After surgery, when resuming warfarin, most patients may resume their preoperative dose. After 3 to 5 days of resuming warfarin, the INR will typically be greater than 2.^{6,7} A loading dose may be given for the first dose if a more rapid resumption of therapeutic coagulation is desired. As a result of this delayed onset of anticoagulation with resuming warfarin therapy, warfarin should be restarted the night of surgery or the morning after.

The yearly rate of thromboembolism is as high as 4.5% for nonvalvular atrial fibrillation (AF),⁸ 8% for mechanical heart valves (MHVs),⁹ 15% for recurrent VTE,¹⁰ and 50% for acute VTE. It has been demonstrated that the risk of thromboembolism is reduced from 66 to 80% with anticoagulation

therapy for common indications, such as acute and recurrent VTE,¹¹ AF,¹² and MHV.⁹ If a patient discontinues warfarin 5 days prior to surgery and resumes warfarin the night after surgery, they can be expected to have approximately 4 days of a subtherapeutic INR, with 2 of these days falling in the postoperative period. Because it has been estimated that major surgery increases the short-term risk of thromboembolism approximately 100-fold,¹³ bridging anticoagulation during this subtherapeutic window has been proposed for certain high- to moderate-risk conditions.

Trials evaluating the rates of thromboembolic events and major bleeding with bridging anticoagulation have provided mixed results. The Prospective Peri-operative Enoxaparin Cohort Trial (PROSPECT) evaluated 260 patients at 24 North American centers on oral anticoagulation for AF or VTE who required invasive procedures or surgery during which the treating physician felt that bridging therapy was necessary.¹⁴ Thromboembolism occurred at a rate of 1.9% with a major bleeding rate of 3.5%. Although this study demonstrated that perioperative bridging with once-daily therapeutic enoxaparin is safe for invasive procedures and minor surgery (bleeding risk < 0.7%), the rate of bleeding for major surgery was 20%.

Kovacs and colleagues performed a prospective, multicenter, single-arm cohort study of 224 patients with MHV and high-risk AF on warfarin therapy who underwent bridging with LMWH.¹⁵ The majority of procedures were cardiac catheterizations, genitourinary surgery, dental procedures, and major orthopedic surgery. Eight patients (3.6%) had an episode of thromboembolism with 15 episodes of major bleeding (6.7%), five of which occurred during postoperative LMWH administration. The bleeding rate for major surgical operations was not specified.

Douketis and colleagues evaluated 650 consecutive patients with an MHV, AF, or embolic stroke who had warfarin held 5 to 6 days before an invasive procedure and received twice-daily dalteparin starting 3 days prior to the procedure.⁷ Warfarin was resumed on the evening of the procedure and twice-daily dalteparin was restarted on postoperative day 1 and continued until the INR reached 2 or greater. For patients undergoing a high-bleeding risk procedure or in whom hemostasis was incomplete, warfarin was resumed on the evening of the procedure, but dalteparin was held or not given after the procedure. In 542 patients who underwent a low-bleeding risk procedure, there was a 0.4% rate of thromboembolism and a 0.7% rate of major bleeding. In 108 patients who underwent a high-bleeding risk procedure, there was a 1.8% rate of thromboembolism and a 1.8% rate of major bleeding. This study included a higher percentage of major surgical operations than the PROSPECT¹⁴ or Kovacs and colleagues' trial¹⁵ and thus is more applicable to elective surgical practices.

The North American REGIMEN investigators conducted a multicenter, observational, prospective trial enrolling 901 patients on oral anticoagulation undergoing an elective surgical or invasive procedure who received either UFH ($n = 180$) or LMWH ($n = 721$) for perioperative bridging.¹⁶ Thromboembolic rates were 2.4% for UFH and 0.9% for LMWH, and rates of major bleeding were 3.3% for UFH and 5.5% for LMWH; neither of these differences was significant. Patients bridged with LMWH were more likely to be able to receive their preoperative heparin therapy as an outpatient. A

Charlson Comorbidity Index score greater than 1 and vascular, general, and major surgery were associated with an increased risk of major bleeding. It should be noted that these trials did not compare the rates of thromboembolic events and major bleeding with those of a control group that did not receive bridging anticoagulation, so it is impossible to determine the relative effect that bridging anticoagulation has on perioperative thromboembolic and bleeding risk.

Either UFH or LMWH can be used for bridging anticoagulation, with LMWH being more cost-effective if the patient is not hospitalized preoperatively for other reasons. UFH should be held at least 4 hours prior to surgery, whereas the last dose of LMWH should be given at most 24 hours prior to surgery. Because of the low risk of bleeding complications in minor surgical or invasive procedures, bridging anticoagulation can be resumed the day after the procedure. However, as noted above, major surgical operations have an increased risk of bleeding with postoperative bridging anticoagulation. Thus, after major surgery, bridging anticoagulation should be held for 2 to 3 days after surgery and hemostasis must be ensured. Alternatively, warfarin therapy can be restarted the day of surgery and postoperative bridging anticoagulation can be withheld altogether as the INR will approach therapeutic levels by 3 days in most people, as previously noted. If hemostasis is not adequate or bleeding occurs, warfarin and bridging anticoagulation should be held until deemed safe by the surgeon. In all cases, especially difficult or unusual cases, contacting the primary care provider or consulting an anticoagulation specialist is always an option.

Determining which patients on warfarin need bridging anticoagulation depends on the risk of thromboembolic events off anticoagulation. There are three major patient populations for whom perioperative bridging anticoagulation is indicated: patients with mechanical heart valves, patients with atrial fibrillation or flutter, and patients with prior VTE. Figures 1 and 2 provide an evidence-based approach for determining which patients with these conditions need bridging anticoagulation.

Perioperative Management of Antiplatelet Therapy

Antiplatelet agents have been increasingly used in patients with elevated cardiovascular or cerebrovascular risk and after cardiovascular and peripheral vascular interventions. The management of these agents in the perioperative setting is a unique challenge for the surgeon as the risk of increased bleeding with antiplatelet therapy and the risk of thrombotic complications related to withholding antiplatelet therapy have not been adequately established. By far, the two most common antiplatelet drugs used in the United States are aspirin and clopidogrel. Aspirin is a cyclooxygenase-1 inhibitor, whereas clopidogrel inhibits the adenosine diphosphate receptor of platelets. Both agents irreversibly inhibit platelet function; therefore, they must be discontinued for 7 to 10 days (the life span of platelets) for significant reversal of their antiplatelet activity to occur prior to surgery. They are usually restarted 24 hours after surgery if hemostasis is adequate.

There is mounting evidence that it is safe to perform minor excisional cutaneous surgery without discontinuing single-agent antiplatelet therapy, including clopidogrel.^{17,18} Surprisingly, there are insufficient data to quantify the risk of bleeding with aspirin or clopidogrel therapy during major

Figure 1 Approach to perioperative anticoagulation. Adapted from Douketis JD et al.⁵⁷ CHF = congestive heart failure; CVA = cerebrovascular accident; DM = diabetes mellitus; HTN = hypertension; TIA = transient ischemic attack; VTE = venous thromboembolism.

noncardiac surgery; however, there are some data to suggest increased bleeding complications with clopidogrel use.¹⁹ In contrast to noncardiac surgery, several studies have characterized the effect of antiplatelet therapy on postoperative bleeding after cardiac surgery. The Department of Veterans

Affairs Cooperative Study on Antiplatelet Therapy randomized 772 patients undergoing coronary artery bypass grafting (CABG) to receive preoperative aspirin versus placebo and found a significant increase in the risk of abnormal postoperative bleeding and the need for reoperation with aspirin.²⁰

		0 points	1.9%/yr

		6 points	18.2%/yr	

Figure 2 CHADS₂ score. Adapted from Gage BF et al.⁵⁸ CHF = congestive heart failure; HTN = hypertension.

Despite this potential for increased bleeding, preoperative aspirin is usually continued during CABG surgery as a result of an improvement in early graft patency.²¹ Clopidogrel use in CABG surgery is associated with an increase in major bleeding, bleeding-related complications, transfusion requirements, and potentially increased use of health care resources.²² However, unlike aspirin, there are no studies demonstrating a benefit of perioperative clopidogrel use prior to elective CABG.

Many large randomized trials have demonstrated a significant risk reduction with the long-term use of antiplatelet agents in patients who are at high risk for atherothrombotic and ischemic cardiac and cerebrovascular events^{8,23} and an increase in ischemic and bleeding events and mortality when these agents are discontinued.²⁴ Thus, in high-risk patients, there is a potential risk reduction in perioperative cardiac and stroke complications with the continuation of antiplatelet drugs during the perioperative period that justifies the potentially increased bleeding risk. Studies that have compared aspirin with clopidogrel²³ or dual aspirin and clopidogrel therapy with aspirin alone²⁵ have failed to show a clinically meaningful increased benefit for cardiovascular risk reduction with clopidogrel used in place of or in addition to aspirin. Because of this, as well as the empirical notion that clopidogrel has a higher bleeding risk than aspirin during surgery, aspirin should be continued in high-risk patients during the perioperative period and clopidogrel should be withheld. Patients who are receiving antiplatelet therapy because of bare metal or drug-eluting stents are a different matter. Premature discontinuation of antiplatelets, in particular clopidogrel, has been shown to increase the risk of in-stent thrombosis. This was demonstrated in a study of patients who underwent noncardiac surgery within 90 days of coronary stenting in which six of seven patients in whom thienopyridine antiplatelet therapy was discontinued prior to noncardiac surgery died postoperatively in a manner suggestive of stent thrombosis, compared with only one of 20 patients in whom the thienopyridine was continued.²⁶ For bare metal stents, dual antiplatelet therapy with aspirin and clopidogrel should be continued for up to 6 weeks to allow for neointimal coverage of the stent, after which time, clopidogrel may be discontinued if necessary prior to surgery.²⁷ For drug-eluting stents, the use of dual antiplatelet therapy

for a period longer than 12 months has not been shown to significantly reduce the rate of myocardial infarction or death from cardiac causes when compared with aspirin monotherapy.²⁸ Thus, for patients requiring surgery 12 months after drug-eluting stent placement, clopidogrel may be stopped as long as aspirin therapy is continued. Figure 3 provides an evidence-based approach for the management of perioperative antiplatelet therapy.

Perioperative VTE Prophylaxis

The Virchow triad describes the three primary contributing factors that lead to thrombosis: stasis, hypercoagulability, and endothelial injury. Surgical patients are frequently immobilized as a result of pain or prolonged bed rest and are generally hypercoagulable because of thromboplastin and tissue factor release after surgical trauma, and many surgical procedures involve the manipulation of blood vessels leading to endothelial injury. Thus, surgical patients are at a particularly increased risk for deep vein thrombosis (DVT) and its most feared complication, pulmonary embolism (PE). VTE rates in surgical patients vary depending on the type of surgery performed and patient-specific risk factors.

The highest rates of VTE in elective surgery occur in patients undergoing hip and knee surgery; asymptomatic DVTs are found in 30 to 60% of patients not receiving thromboprophylaxis who undergo routine screening with postoperative venography.²⁹ In general surgery patients undergoing elective abdominal surgery not receiving thromboprophylaxis, the rates of asymptomatic DVT range from 15 to 40%.³⁰ However, despite the high rate of asymptomatic DVTs reported in many studies that use routine screening, the rates of symptomatic DVT and PE are much lower. Unpublished data using the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) data set, which contains information on 363,884 patients who underwent surgery from 2005 to 2007 from 186 participating hospitals, provide an average rate of clinically significant DVT and PE in surgical patients of 0.96%. Using the Nationwide Inpatient Sample, Mukherjee and colleagues evaluated the VTE rates for various abdominal operations and found surprising results.³¹ Bariatric surgery, a procedure felt to be a high risk for VTE given the presence of significant

Figure 3 Approach to perioperative antiplatelet therapy.

patient risk factors, namely obesity, had, surprisingly, the lowest risk of VTE among the procedures studied, at 0.35%. VTE rates were 0.85% for nephrectomy, 1.76% for hepatectomy, 2.36% for splenectomy, 2.58% for gastrectomy, 2.91% for pancreatectomy, and 3.66% for esophagectomy. When multivariate analysis was performed to adjust for nonprocedural risk factors, bariatric surgery still had a lower likelihood of developing VTE [see Table 1]. Also in this study, mortality was 3.5 times higher in those who developed VTE than those who did not, and VTE was nearly 3 times as common following nonelective procedures compared with elective procedures. Certain low-risk procedures do not require VTE prophylaxis because of a low risk of thrombotic events. For example, the risk of DVT or PE complications in thyroidectomy and parathyroidectomy patients is very low at 0.16%, with a risk of bleeding requiring a return to the operating room that is 10-fold higher. VTE prophylaxis should be reserved for only the highest risk patients undergoing these procedures.³²

The rationale for VTE prophylaxis for high-surgical risk patients is based on the high prevalence of VTE complications for many surgical procedures; the excess morbidity, mortality, and cost attributed to these complications; and the safety, efficacy, and cost-effectiveness of VTE prophylaxis in

Table 1 Odds of Developing Venous Thromboembolism by Surgical Procedure Relative to Bariatric Surgery*

Procedure	All Procedures	Elective Procedures Only
Nephrectomy	1.19	1.0
Colorectal surgery	1.87	1.62
Pancreatectomy	2.07	1.46
Gastrectomy	2.44	1.68
Esophagectomy	2.47	2.06
Hepatectomy	2.55	2.13
Splenectomy	2.69	2.27

* Adjusted for age, gender, year, Charlson Comorbidity Index score, length of stay, hospital teaching status, elective procedure status, trauma, and malignancy.

reducing these complications. The high prevalence of VTE complications has already been demonstrated in the previous paragraph. The incidence of fatal PE in general surgery patients is as high as 0.9%,³³ and the development of VTE can increase the median length of stay by as much as 11 days,

with an increase in median total hospital charges of up to \$50,000 for each event.³¹ Collins and colleagues reviewed 46 randomized trials of perioperative subcutaneous heparin that included nearly 13,000 patients who underwent general, orthopedic, and urologic surgery.³⁴ They found a 68% reduction in DVT, a 67% reduction in PE, and a 21% reduction in total mortality after surgery in patients who received perioperative heparin prophylaxis compared with controls, with a small increase in bleeding (5.9% compared with 3.8% for controls), most of which were not clinically significant. A systematic review of 33 randomized, controlled trials examined the rates of bleeding complications with pharmacologic VTE prophylaxis and found that bleeding complications requiring a change in care occur less than 3% of the time and major bleeding complications, such as gastrointestinal tract (0.2%) or retroperitoneal (< 0.1%) bleeding, were infrequent.³⁵ In cost-effectiveness studies, VTE prophylaxis has been found to be more cost-effective than no prophylaxis in orthopedic surgery, trauma, and general surgery.³⁶ Mamdani and colleagues demonstrated in abdominal surgery patients that overall costs (including costs of labor) associated with surgical prophylaxis with conventional low-dose heparin, dalteparin, and intermittent pneumatic compression (IPC) were \$84, \$122, and \$102, respectively, compared with \$112 for no prophylaxis.³⁷ Compared with no prophylaxis, the cost per mortality prevented was \$6,087 for conventional low-dose heparin, \$3,125 for IPC, and \$2,857 for dalteparin.

Despite the lower risk of VTE in bariatric surgery, bariatric surgeons have performed exceptionally well in adhering to thromboprophylaxis guidelines, with one study demonstrating a 95% adherence rate.³⁸ This is in contrast to the findings of the ENDORSE trial, a multinational cross-sectional survey that assessed the prevalence of VTE in the acute hospital care setting and the proportion of at-risk patients who receive appropriate prophylaxis based on American College of Chest Physicians (ACCP) criteria.³⁹ The authors found that 64.4% of all surgical patients were at risk for VTE, and of the surgical patients at risk, only 58.5% received ACCP-recommended VTE prophylaxis. Interestingly, of the surgical patients who were deemed to be at low risk for VTE, 34% received VTE prophylaxis that was not indicated. The proportion of patients receiving appropriate prophylaxis varied from 88% of patients undergoing hip or knee replacement to 69% of those undergoing colorectal surgery and 50% undergoing urologic procedures.

Clearly, passive strategies to promote adherence to VTE prophylaxis guidelines have not been successful. The ACCP evidence-based practice guidelines have provided four recommendations for hospital prophylaxis policy: for every general hospital, a formal, active strategy should be developed that addresses the prevention of VTE; the local thromboprophylaxis strategy should be in the form of a written, institution-wide thromboprophylaxis policy; strategies shown to increase thromboprophylaxis adherence should be adopted, including computer decision support systems, preprinted orders, and periodic audit and feedback; and passive methods, such as distribution of educational materials or educational meetings, are not recommended as sole strategies to increase adherence to thromboprophylaxis.³⁰ It is imperative that surgeons be active participants in their local institutional prophylaxis policy. An example of an institutional VTE policy is included in Table 2.

Table 2 Venous Thromboembolism Risk Assessment

1 Point Age 41–60 yr Procedure with local anesthesia Prior surgery (< 1 mo) History of inflammatory bowel disease Obesity (BMI 30–39) Acute myocardial infarction (< 1 mo) Heart failure exacerbation (< 1 mo) Swollen legs (current) Sepsis (< 1 mo) Serious lung disease, e.g., pneumonia (< 1 mo) Any patient currently on bed rest Leg plaster cast or brace 1 Point (for women only) Oral contraceptives or hormone replacement therapy Pregnancy or postpartum (< 1 mo) History of unexplained stillborn infant, spontaneous abortion (≥ 3), premature birth with toxemia, or growth-restricted infant 2 Points Age 61–74 yr Surgery lasting < 2 hr History of malignancy Central venous access Morbid obesity (BMI 40–49) 3 Points Age ≥ 75 yr History of SVT, DVT/PE Surgery lasting 2–3 hr BMI ≥ 50 Present cancer or chemotherapy Established thrombophilia 5 Points Elective lower extremity arthroplasty Hip, pelvis, or leg fracture (< 1 mo) Stroke (< 1 mo) Multiple trauma (< 1 mo) Acute spinal cord injury (< 1 mo) Surgery lasting > 3 hr		
Total Risk Factor Score	Risk Level	Prophylaxis Regimen
0–1	Low	Early and frequent ambulation
2	Moderate	Heparin 5,000 units SC every 8–12 hr
3–4	High	Heparin 5000 units SC every 8 hr OR LMWH SC (e.g., dalteparin 5000 units every 24 hr) ± Sequential compression devices OR Knee-high antiembolism stockings
≥ 5	Highest risk	Heparin 5,000 units SC every 8 hr OR LMWH SC (e.g., dalteparin 5,000 units every 24 hr) AND Sequential compression devices OR Knee-high antiembolism stockings

BMI = body mass index; DVT = deep vein thrombosis; PE = pulmonary embolism; SC = subcutaneous; SVT = supraventricular tachycardia.

The type of anticoagulant used for prophylaxis depends on institutional or surgeon preference and patient factors. The two most commonly used anticoagulants are low-dose unfractionated heparin (LDUH) and LMWH. The efficacy of LDUH compared with no prophylaxis was convincingly demonstrated in the Collins and colleagues' meta-analysis, with the three times daily dosing being more efficacious than twice-daily dosing, without an increase in bleeding complications.³⁴ LMWH has also been shown to reduce VTE compared with no prophylaxis, with one meta-analysis showing a significant reduction in clinical VTE and a trend toward a reduction in the overall mortality rate. Higher doses of LMWH improved efficacy but increased the rates of bleeding, including major bleeding events.⁴⁰ Comparisons between LDUH and LMWH have not demonstrated one to be superior to the other in terms of efficacy for general surgical procedures. Figure 4 provides an evidence-based approach to the perioperative management of VTE prophylaxis in general surgery patients.

Koch and colleagues performed a publication-based meta-analysis of 36 double-blind studies comparing LDUH and LMWH for surgical prophylaxis.⁴¹ LDUH and LMWH had similar efficacy in general surgery patients, and LDUH had a decreased bleeding rate compared with higher-dose LMWH and an increased bleeding rate compared with lower-dose LMWH. The same group performed a meta-analysis based on original patient data and confirmed these findings, including a significantly lower risk of wound hematoma in low-dose LMWH compared with LDUH.⁴² In both studies, LMWH was more efficacious compared with LDUH in orthopedic patients. LMWH is also the standard of care for major trauma patients given its demonstrated superiority and equivalent bleeding risk compared with LDUH.⁴³

Fondaparinux, a synthetic pentasaccharide factor Xa inhibitor, also has been proven efficacious for VTE prophylaxis

both in placebo trials⁴⁴ and in comparison with LMWH.⁴⁵ The benefits of LDUH include reduced costs, its ability to be used in patients with renal failure, its shorter half-life, and its safety in patients with regional blocks and epidural catheters. LMWH and fondaparinux require less frequent dosing and may have a lower incidence of wound hematomas (for low-dose LMWH) and a lower risk of heparin-induced thrombocytopenia. However, the factor Xa inhibitors require renal and weight-based dosing and are contraindicated in patients with a creatinine clearance less than 30 mL/min. Newer agents, such as the orally active direct factor Xa inhibitor rivaroxiban, have been shown to be significantly more effective than once-daily LMWH (with equivalent safety) in patients undergoing elective total hip arthroplasty⁴⁶ and total knee arthroplasty.⁴⁷ These agents are promising for both their increased efficacy and the ease of continuing oral dosing after discharge from the hospital for extended prophylaxis.

Of the surgical patients found to be at risk for VTE in the ENDORSE trial, 9% were considered to have a bleeding risk high enough to be considered a contraindication to anticoagulant prophylaxis.³⁸ In patients who are at a high bleeding risk and also at risk for VTE who would otherwise be treated with anticoagulant prophylaxis, mechanical methods of thromboprophylaxis, such as graduated compression stockings, IPC, or venous foot pumps, should be used. Once the bleeding risk has resolved, anticoagulant prophylaxis can be substituted or added to mechanical prophylaxis.

The initiation of VTE prophylaxis is particularly challenging in multisystem trauma because of concomitant bleeding risks from intracranial, abdominal, thoracic, retroperitoneal, and spinal injuries. Furthermore, competing input from consulting services and the need for numerous surgical interventions can delay the initiation of VTE prophylaxis. Because of these challenges, a VTE prophylaxis protocol should be

Figure 4 Approach to perioperative venous thromboembolism (VTE) prophylaxis: general surgery. Adapted from Geerts WH et al.³⁰ GCS = graduated compression stocking; IPC = intermittent pneumatic compression; LDUH = low-dose unfractionated heparin; LMWH = low-molecular-weight heparin.

instituted at any center that takes care of the multiply injured trauma patient. In trauma patients, there is evidence that VTE prophylaxis does not need to be withheld for most injuries, including traumatic brain injury, if ongoing hemorrhage has been ruled out. Cothren and colleagues placed patients at high risk for VTE, including patients with stable intracranial injuries, on a protocol that initiated once-daily dalteparin an average of 3 days postinjury and continued it through most surgical procedures.⁴⁸ This allowed a daily, uninterrupted prophylaxis regimen in 74% of patients and an overall DVT rate of 3.9%, a PE rate of 0.8%, a wound complication rate of 2.7%, blood transfusions in 3%, and no exacerbations of intracranial bleeding or deaths as a result of hemorrhage. Figure 5 provides an evidence-based approach to perioperative VTE prophylaxis in the trauma patient.

Prophylactic inferior vena cava (IVC) filters have been increasingly used over the last decade⁴⁹ as a result of the

advent of retrievable filters. Two groups that have seen the largest increase in prophylactic IVC filter placement are bariatric patients and multisystem trauma patients, particularly acute spinal cord injury (SCI) patients. As discussed previously, bariatric surgery patients do not have a higher risk of VTE events compared with other surgical patients, and the risk of a fatal PE after bariatric surgery is 0.2%.⁵⁰ Given that the vast majority of bariatric patients are able to receive perioperative thromboprophylaxis, prophylactic IVC filter placement in this population is not warranted. In fact, not only do prophylactic IVC filters for gastric bypass surgery not reduce the risk of pulmonary embolism, they may also lead to additional complications.⁵¹ In contrast to bariatric surgery, multisystem trauma does confer a greater risk of VTE complications. Furthermore, trauma patients are more likely to have a contraindication to anticoagulation, leading to a potential delay in the initiation of prophylaxis.

Figure 5 Approach to perioperative venous thromboembolism (VTE) prophylaxis: trauma. Adapted from Geerts WH et al.³⁰ DUS = duplex ultrasonography; GCS = graduated compression stocking; IPC = intermittent pneumatic compression; LDUH = low-dose unfractionated heparin; LE = lower extremity; LMWH = low-molecular-weight heparin.

The premise behind prophylactic IVC filters in trauma patients is to protect patients from a PE while they are not able to receive anticoagulation. However, there are no randomized, controlled trials demonstrating the efficacy of prophylactic IVC filters in trauma patients. Furthermore, complication rates for IVC filter placement are surprisingly high. In a review of the current literature up to 2005, the complication rate for prophylactic IVC filters was 13%, with a 1% rate of PEs (40% of these being fatal), a 2% rate of IVC thrombosis and occlusion, a 2% rate of insertion-site thrombosis, and a 1% risk each for filter migration, filter misplacement, and filter tilt.⁵² These rates are comparable to those in more recent studies conducted by experienced practitioners. Each of these complication rates exceeds the rates of PE in trauma patients (0.27 to 0.48%),^{53,54} Prophylactic IVC filters in high-risk patients who cannot receive pharmacologic prophylaxis were found to increase the risk of DVT in one study and were not cost-effective compared with serial duplex ultrasound screening, which was associated with better clinical outcomes and lower costs.⁵⁵ Patients with acute SCI represent perhaps the highest-risk group in terms of VTE risk. However, the incidence of VTE in SCI patients is similar to that of the overall trauma population when appropriate DVT prophylaxis is used, making routine placement of prophylactic caval filters unnecessary.⁵⁶ Patients

in whom prophylactic IVC filters may be appropriate include SCI patients with long bone and pelvic fractures, patients with DVT formation despite prophylactic anticoagulation, and patients with contraindications to anticoagulation and a DVT documented on serial duplex ultrasound screening.

Patients receiving LDUH for VTE prophylaxis should have the first dose administered 1 to 2 hours prior to general anesthesia as most of the LDUH thromboprophylaxis trials used this regimen and it is thought that the risk of VTE starts with the onset of general anesthesia. VTE prophylaxis for most patients should be continued until hospital discharge or for at least 7 days postoperatively as this is the time when most VTE events occur. However, certain high-risk groups are at risk for late VTE events and should receive extended VTE prophylaxis after hospital discharge. These patients include major cancer surgery patients and patients who have previously had a VTE (VTE prophylaxis up to 28 days after surgery); patients undergoing hip or knee replacement surgery (VTE prophylaxis from 10 to 35 days after surgery); major trauma patients (VTE prophylaxis continued during inpatient rehabilitation); and patients with acute SCI (VTE prophylaxis for at least 3 months or until the completion of inpatient rehabilitation).³⁰

33 PERIOPERATIVE MANAGEMENT OF PATIENTS ON STEROIDS REQUIRING SURGERY

Alexandra Reiher, MD, and Rebecca S. Sippel, MD, FACS

Perioperative glucocorticoid replacement therapy can be challenging, but appropriate replacement is essential to optimize the patient's outcome. Intermittent and chronic steroid use results in decreased adrenocorticotrophic hormone (ACTH) secretion by the pituitary gland, which over several weeks results in adrenal gland atrophy, eventually leading to secondary adrenal insufficiency.¹ Patients with chronic lung disease, inflammatory bowel disease, rheumatoid arthritis, and solid-organ transplantations are often on steroid supplementation either intermittently or chronically. Determining which of these patients requires high-dose steroids perioperatively can be difficult. Insufficient dosing of glucocorticoids during the perioperative period can result in hypotension and even death. Excessive treatment with glucocorticoids decreases wound healing and increases susceptibility to infection, among a myriad of other complications. This chapter provides guidelines toward evaluation and treatment of secondary adrenal insufficiency during the perioperative period.

Historical Perspective

Iatrogenic adrenal insufficiency was first identified in 1952 by Fraser and colleagues.² A patient on chronic steroids underwent surgery and subsequently developed acute adrenal crisis attributable to preoperative withdrawal from glucocorticoid therapy. A similar case was reported by Lewis and colleagues in 1953.³ A patient who had surgical repair for a flexion contracture of the right knee died a few hours after surgery. The patient had been on cortisone daily for 5 months before surgery, but his cortisone had been held the day prior to and the day of his surgery. A postmortem examination revealed diffuse atrophy and hemorrhage of the adrenal glands, confirming the diagnosis of adrenal insufficiency. The authors then published the first set of guidelines regarding perioperative glucocorticoid management. They recommended increasing glucocorticoids fourfold to avoid intraoperative hypotension and death. These recommendations are probably what has led us to overtreat most patients today. We now know that this dose is in great excess to the normal physiologic response to surgery.

Hypothalamic-Pituitary-Adrenal Axis

The hypothalamic-pituitary-adrenal (HPA) axis is activated during acute physical or emotional stress. Corticotropin-releasing hormone (CRH) is secreted by the hypothalamus as a result of stimulation by serotonin. CRH secretion is

inhibited by noradrenaline and cortisol. CRH secretion results in secretion of plasma ACTH from the pituitary gland, stimulating secretion of cortisol from the zona fasciculata in the adrenal glands [see Figure 1]. ACTH is also stimulated by adrenaline. Normal basal secretion of cortisol by the adrenal gland is 8 to 10 mg/day.⁴ A study using stable isotope dilution thermospray liquid chromatography–mass spectrometry confirmed that the average cortisol production rate per day was approximately 9.9 mg.⁵

During a minor procedure or surgery, the adrenal gland produces up to 50 mg/day of cortisol.^{6,7} A study by Plumpton and colleagues evaluated plasma cortisol levels in patients during and after major and minor surgeries.⁷ In patients undergoing major surgery, cortisol levels initially fell after premedication, followed by a rapid rise during surgery and a further rise in cortisol during the early postoperative period. A similar pattern of response was seen in patients undergoing minor surgeries, but with a smaller peak. Peak values occur within 4 to 6 hours after surgery or injury and return to baseline after 24 hours.⁸ After major surgery, such as cardiac surgery, cortisol secretion is 75 to 100 mg on the first day and can remain elevated for 48 to 72 hours.⁶ Secretion rates greater than 200 mg/day within the first 24 hours of surgery are rare.

Figure 1 Hypothalamic-pituitary-adrenal axis. ACTH = adrenocorticotrophic hormone; CRH = corticotropin-releasing hormone.

Assessing a Patient's HPA Axis

BASELINE CORTISOL LEVELS

Determining whether a patient's HPA axis is functioning is the first step to deciding if glucocorticoid supplementation is indicated during the perioperative period. Random serum cortisol levels are of little utility because of diurnal variation, but early-morning serum cortisol levels drawn between 7 and 9 am will reflect maximal secretion. Morning cortisol levels of 18 to 20 µg/dL reflect an intact adrenocortical reserve. No further testing is needed in these patients.⁹ A morning cortisol level below 3 µg/dL strongly suggests adrenal insufficiency, and the level should be repeated. If it remains low, physiologic steroid replacement should be initiated, and no further testing is necessary. Patients with baseline cortisol levels between 3 and 11 µg/dL benefit from an additional workup for adrenal insufficiency to clarify their adrenal function. Dynamic testing is useful in this setting to determine a patient's ability to produce cortisol in response to stress or ACTH stimulation¹⁰ [see Figure 2].

Serum cortisol reflects primarily protein-bound cortisol levels. Estrogen, which increases cortisol-binding globulin, increases total cortisol concentrations. This can lead to falsely elevated cortisol levels. Low serum albumin concentrations can cause falsely low total serum cortisol levels, even though they have normal biologically active free cortisol concentrations. Measuring serum free (unbound) cortisol levels is thus more accurate in these patients.⁹

INSULIN-INDUCED HYPOGLYCEMIA

The insulin-induced hypoglycemia test is considered the gold standard but is rarely used today because of the associated risks, including coma and seizures. This test involves

administering intravenous (IV) insulin (0.10 to 0.15 units/kg) to a fasting patient until hypoglycemia (blood glucose < 40 mg/dL) is achieved. A normal stress response to hypoglycemia will elicit an increase in serum cortisol.⁹ A patient with an intact HPA axis will have a rise in cortisol to at least 18 to 20 µg/dL.¹¹ This must be performed in a controlled setting, preferably an experienced endocrine clinic with close supervision.

ACTH STIMULATION TEST

The ACTH stimulation test is more commonly used to determine adrenal function. Synthetic ACTH (cosyntropin [Cortrosyn]) is administered intravenously in a dose of 250 µg. Baseline, 30-minute, and 60-minute cortisol levels are obtained. Normal adrenal function will produce a peak cortisol of at least 18 to 20 µg/dL and typically a delta of more than 8 to 10 µg/dL. The delta level (change from baseline) is not recommended as the sole determinant of adequate response to ACTH stimulation. An expected delta of 8 to 10 µg/dL in the setting of a peak cortisol lower than 18 µg/dL should still be considered an abnormal response.¹²

Performing an ACTH stimulation test in the morning yields the best results. It is important to hold exogenous steroids for 24 hours prior to the test, and longer-acting glucocorticoids, such as prednisone, should be held for 5 to 7 days. This dose of cosyntropin is supraphysiologic and can stimulate cortisol levels to the normal range in a patient with partial adrenal insufficiency. A low-dose cosyntropin stimulation test with 1 µg can be performed to better evaluate patients with partial adrenal suppression or central adrenal insufficiency but is not currently recommended because of a need for further studies to determine the efficacy of this test. Also, this low dose of cosyntropin is not commercially

Figure 2 Algorithm for evaluation of the patient on steroids in the perioperative period. ACTH = adrenocorticotrophic hormone.

available, and serial dilutions are therefore required. This is both inconvenient and has the potential for inconsistent dosing.¹³

The ACTH stimulation test is easier to perform than the insulin tolerance test, requires less supervision, and does not carry the risks associated with inducing hypoglycemia. The ACTH stimulation test has been shown to have a close correlation with the insulin tolerance test ($r = .92$; $p < .0001$).¹⁴ The ACTH stimulation test is the recommended test for evaluating adrenal insufficiency.

When to Suspect an Impaired HPA Axis

PATIENTS CURRENTLY ON ORAL STEROIDS

The exact time period it takes for a patient to become adrenally suppressed while treated with glucocorticoids, and the time it takes to recover adrenal function after discontinuation of steroids, is not known. When evaluating for HPA suppression, one needs to consider both the dose and the duration of previous glucocorticoid therapy. In general, any patient who has received doses equivalent to 20 mg of prednisone for more than 5 days is at risk for suppression of the HPA axis. If the glucocorticoid doses are closer to but above the physiologic range, 1 month is likely the minimal interval. For patients on chronic steroids, if the dose is equivalent to 5 mg or less of prednisone daily [see Table 1 for steroid conversions], these patients have a normal response to HPA testing and do not require additional glucocorticoid treatment perioperatively. Patients receiving between 5 and 20 mg of prednisone daily (or an equivalent dose of another steroid) should undergo further testing.¹⁵ Patients receiving alternate-day glucocorticoid treatment (a short-acting glucocorticoid given every 48 hours, in the morning) tend to have less adrenal suppression than patients taking steroids on a daily basis. These patients should be evaluated for adrenal suppression as the response is not the same between patients.¹³

PATIENTS USING INHALED STEROIDS

A meta-analysis by Masoli and colleagues evaluated adrenal function in patients receiving inhaled corticosteroids.¹⁶ Many studies were eliminated because of insensitive measurements for testing the HPA axis, lack of placebo control, and inclusion of patients on oral steroids. Five randomized, controlled studies were analyzed. Patients receiving therapeutic doses of inhaled fluticasone (50 to 500 µg/day) were found to have minimal abnormal responses to a cosyntropin stimulation test. Four percent of patients had an abnormal response

to adrenal function testing. For each 500 µg/day increase in a patient's fluticasone dose, the odds ratio of an abnormal adrenal function test increased 1.4-fold. It is necessary to consider adrenal suppression in all patients on inhaled corticosteroids, particularly those receiving supratherapeutic doses.

PATIENTS USING TOPICAL STEROIDS

Although it is unknown what potency or dose of topical steroid can induce secondary adrenal suppression, the risk associated with topical steroids must be assessed. The following factors increase the risk of adrenal suppression: application to a large surface area of skin, long-term use, associated use of occlusive dressings, and use of high-potency (class I) glucocorticoid agents.¹⁷

PATIENTS PREVIOUSLY ON STEROIDS

Multiple studies have shown normal adrenal responses within 3 weeks of discontinuing short-term glucocorticoid therapy. It would therefore be safe to assume that recovery from suppression may be incomplete for approximately 2 months after glucocorticoid treatment. For patients who have had prolonged exposure to high doses of glucocorticoids, recovery can take up to 1 year. These patients should undergo formal testing, preferably an ACTH stimulation test, to determine adrenal responsiveness. A normal response eliminates the need for perioperative glucocorticoid supplementation.^{7,13} However, should such a patient develop hypotension perioperatively, there should be a low threshold to administer a dose of IV hydrocortisone. Obtaining a complete history regarding current and past use of glucocorticoids is necessary to avoid potential adrenal crisis in the perioperative period.

PATIENTS WITH KNOWN PRIMARY ADRENAL INSUFFICIENCY

Patients with primary adrenal insufficiency require both mineralocorticoid and glucocorticoid replacement therapy. The most common cause of primary adrenal insufficiency in the United States is autoimmune adrenal insufficiency, or Addison disease. A thorough review of a patient's medical history should elicit this information. These patients often have hyperpigmentation of their skin and mucosa because of elevated plasma β-lipotropin concentrations (derived from pro-opiomelanocortin) and increased synthesis of melanin by melanocytes.⁹ Patients with primary adrenal insufficiency typically take fludrocortisone 0.05 to 0.1 mg once daily, as well as hydrocortisone 15 mg daily divided into two to three doses (typically 10 to 15 mg in the morning and 5 to 10 mg in the evening).¹⁸ Glucocorticoid replacement must be continued in the perioperative period because of primary disease of the HPA axis. If a patient with primary adrenal insufficiency is receiving hydrocortisone in excess of 100 mg/day, mineralocorticoid supplementation can be held. Hydrocortisone has both mineralocorticoid and glucocorticoid properties at high doses. However, once the glucocorticoids are tapered to below 100 mg/day, fludrocortisone must be restarted.

Argument against Supraphysiologic Glucocorticoid Treatment in the Perioperative Period

Weighing the risks and benefits of glucocorticoid supplementation for surgery is quite difficult. The complications associated with high-dose glucocorticoids are well known,

Table 1 Steroid Conversions

Medication	Approximate Equivalent Dose (mg)	Relative Potency
Cortisol	20	1.0
Hydrocortisone	25	0.8
Prednisone	5	4.0
Prednisolone	5	4.0
Methylprednisolone	4	5.0
Dexamethasone	0.75	30–150
Triamcinolone	4	5.0

including hyperglycemia, impaired wound healing, and hypertension. In the postoperative setting, patients treated with steroids are at increased risk for decreased tissue repair rates and increased susceptibility to infections.¹⁹ Numerous studies have been performed over the past 30 years challenging the theory that patients on chronic steroids need additional steroids perioperatively. The reported incidence of perioperative adrenal insufficiency is rare, estimated at 0.01 to 0.7%.^{20,21}

Kehlet and Binder evaluated 104 glucocorticoid-treated patients undergoing surgery without supplemental stress doses of glucocorticoids.²² Glucocorticoid therapy was withheld 36 hours before surgery and restarted 24 hours after minor surgery and 72 hours after major surgery. Plasma corticosteroid doses were measured during the 24-hour postoperative period. The mean corticosteroid value 1 hour after skin incision increased significantly from baseline. This response was impaired in 39 patients undergoing major surgery (53%) compared with the control group. Seven episodes of hypotension were noted, all of which responded spontaneously or to fluid administration. All hypotensive episodes lasted less than 20 minutes. Nine patients undergoing minor surgery (30%) had an abnormal corticosteroid response. One patient undergoing minor surgery developed unexplained intraoperative hypotension. This patient had severe adrenocortical failure and responded to 50 mg of hydrocortisone along with fluid resuscitation.

A study by Udelsman and colleagues evaluated glucocorticoid replacement in the perioperative period on adrenalectomized primates.²³ Primates were given glucocorticoid replacement for 4 months after adrenalectomy. The monkeys were then stratified to receive different quantities of glucocorticoid replacement for 4 days prior to surgery: subphysiologic (one tenth the normal cortisol production rate), physiologic, or supraphysiologic (10 times the normal cortisol production rate). Sham adrenalectomized placebo-treated animals served as controls. The monkeys then underwent a cholecystectomy. The subphysiologically treated group was hemodynamically unstable before, during, and after surgery and had a significantly higher mortality rate than controls. However, the physiologically replaced group had intraoperative hemodynamics and postoperative outcomes similar to those of the supraphysiologically treated and sham-operated controls. This study suggests that replacing physiologic doses of glucocorticoids is sufficient for glucocorticoid replacement for moderate surgery in primates.

The need for high-dose steroids during orthopedic surgery was evaluated by Friedman and colleagues.¹⁵ The authors performed a prospective study of 28 patients on chronic, immunosuppressive doses of glucocorticoids who were undergoing major orthopedic operations. The patients were given their baseline doses of glucocorticoids (mean dose 10 mg prednisone), with no additional stress doses of steroids. Twenty-four-hour urinary free cortisol levels were obtained perioperatively and postoperatively. No evidence of adrenocortical insufficiency was documented. Seventy-one percent of patients demonstrated increased production of endogenous corticosteroids (urinary level of free cortisol) in response to the operative stress.

These studies by Kehlet and Binder, Udelsman and colleagues, and Friedman and colleagues all independently provide clinical evidence that supraphysiologic doses of

glucocorticoids in the perioperative period are likely of little benefit. The study by Kehlet and Binder provides evidence that it is necessary to continue glucocorticoids during the perioperative period as withholding glucocorticoids may result in hypotension.²² Udelsman and colleagues demonstrated that subphysiologic doses are not sufficient in the perioperative period either.²³ However, continuing a patient's outpatient glucocorticoid regimen during the perioperative period may be safe for minor or moderate surgeries based on recent clinical evidence.

Why Treat Patients with Impaired Adrenal Function?

Patients with normal adrenal function have increased secretion of plasma ACTH and cortisol concentrations, urinary free cortisol, and concentrations of urinary metabolites of cortisol when faced with surgery, trauma, or critical illness. The HPA response to surgical stress has a considerable inter-individual variation.¹⁹ Thus, it is necessary to cover a patient with impaired adrenal function sufficiently, but exactly how much coverage is needed is not entirely understood. The goal of treatment with glucocorticoids is to provide an amount equivalent to the normal physiologic response to surgical stress while avoiding overtreatment. To determine a proper dose replacement, one must consider the patient's adrenal status, as well as the severity and duration of surgery.

Guidelines for Dosing Glucocorticoids in the Perioperative Period

Once it is determined that a patient will require perioperative glucocorticoid replacement, the dose of glucocorticoids must be determined. Optimal dosing will mimic a normal physiologic response to surgical stress. Three factors will determine the dose of glucocorticoids required: the preoperative dose of glucocorticoid, the preoperative duration of glucocorticoid use, and the anticipated duration of surgery. Surgeries that require a longer duration or greater physiologic stress, such as cardiothoracic surgery, require a higher dose of glucocorticoid supplementation.¹⁹ IV steroids should be continued in all cases until a patient is able to tolerate enteral feeding. Should a patient develop postoperative complications and require close monitoring in the hospital, stress-dose steroids should be administered.

MINOR SURGERY

Minor surgeries, which include those lasting less than an hour, do not require additional glucocorticoid administration. Inguinal hernia repair, scheduled cardiac catheterization, and laparoscopic cholecystectomy are some examples of minor surgery. Patients should be instructed to continue their home regimen of steroids through the perioperative period, including the day of surgery. The HPA axis to minor surgery is minimal; additional steroid supplementation is not indicated.¹⁹

MODERATE SURGERY

For moderate surgeries, including nonlaparoscopic abdominal surgeries and total joint replacement, patients should receive their outpatient steroid dose preoperatively (either intravenously or by mouth). Hydrocortisone 50 mg IV should be administered intraoperatively, followed by hydrocortisone

25 mg IV twice daily for 24 to 48 hours postoperatively. Patients can return to their preoperative doses (either enterally or parenterally) on postoperative day 2 and, once tolerating oral feeding, can be continued on their outpatient glucocorticoid regimen.

MAJOR SURGERY

Major surgeries, including pancreatoduodenectomy, cardiac surgeries requiring cardiac bypass, and total proctocolectomies, require higher doses of glucocorticoids intraoperatively and postoperatively. The target glucocorticoid dosing is 100 to 150 mg of hydrocortisone per day (or another glucocorticoid in equivalent dosing) for 2 to 3 days. For example, hydrocortisone 50 mg every 8 hours for 72 hours. Stress-dose steroids can be initiated on the day of surgery, immediately prior to anesthesia induction. Once the patient is tolerating an enteral diet and is no longer in a critical condition, steroids can quickly be tapered to the outpatient regimen.

Table 2 provides an outline of recommended steroid replacement in the perioperative period based on the nature of surgery being performed. Recommendations are based on expert opinion.

Consulting a Specialist

Patients with suspected or known adrenal insufficiency attributable to pituitary disease should be followed by an endocrinologist as it is more difficult to assess the HPA axis in these patients. Endocrinologists can help with interpretation of ACTH stimulation tests that have produced confusing results. There are no clear guidelines on steroid tapering, but a slower taper should be initiated for complicated surgeries or patients with longer hospital stays postoperatively, and a specialist can help formulate the taper. A patient being treated for Cushing disease with pituitary or adrenal surgery must be followed by an endocrinologist. The endocrinologist can provide guidelines for a slow steroid taper after surgery and will likely follow the patient after hospital discharge in the clinic.

Conclusion

A patient with an intact HPA axis will mount a cortisol response to surgery or other stressors. The goal of glucocorticoid replacement in patients without an intact HPA is to mimic normal adrenal function. Most patients undergoing minor surgeries can continue their outpatient glucocorticoid

regimens alone. For patients undergoing moderate or major surgeries, their adrenal function needs to be determined, and an appropriate dose of glucocorticoids should then be administered. Although adrenal insufficiency in the perioperative setting is rare, it is easily avoided with a good history regarding prior steroid use within the previous year. It is important to ask patients regarding inhaled and topical steroids as well as these can impact adrenal function. Below are a few case examples for further review:

Case 1. A 51-year-old man with rheumatoid arthritis on prednisone 5 mg every other day chronically is undergoing a laparoscopic cholecystectomy.

Answer. The patient should take 5 mg prednisone the morning of surgery. If his postoperative course is uncomplicated, he can resume his outpatient glucocorticoid regimen.

Case 2. A 30-year-old woman with Crohn disease on prednisone 10 mg daily for the last 6 months is undergoing a total abdominal hysterectomy for fibroids.

Answer. The patient should receive prednisone 10 mg daily prior to surgery followed by hydrocortisone 50 mg IV intraoperatively. Postoperatively, continue hydrocortisone 25 mg IV every 12 hours. The patient can be transitioned to either prednisone 10 mg daily on postoperative day 2 if tolerating an oral diet or continue hydrocortisone 25 mg IV every 12 hours until the patient is tolerating enteral feeding.

Case 3. A 60-year-old man with chronic obstructive lung disease who has required frequent steroid burst over the past year is undergoing three-vessel cardiac bypass surgery.

Answer. Although the patient is not currently on glucocorticoids, he likely has an abnormal HPA axis. Prior to surgery, it would be appropriate to perform an ACTH stimulation test.

If his peak cortisol level is only 12 µg/dL, the patient should take an outpatient dose of glucocorticoid the morning of surgery. The patient should receive 50 mg IV intraoperatively and then stress-dose steroids: hydrocortisone 150 mg IV daily for 2 to 3 days (50 mg every 8 hours). After this time period, his dose can be quickly tapered to his outpatient regimen.

Table 2 Perioperative Glucocorticoid Treatment Recommendations^{13,19}

Surgery	Definition	Recommended Glucocorticoid Dose (in patient on chronic glucocorticoids or with abnormal ACTH-stimulation test)
Minor	Local anesthesia; surgery less than 1 hour duration	Continue outpatient regimen; no additional steroids needed
Moderate	Joint replacement; lower extremity revascularization	Take outpatient dose morning of surgery. Give hydrocortisone 50 mg intraoperatively (or equivalent); continue hydrocortisone 25 mg IV every 12 hours for 24–48 hours postoperatively.
Major	Cardiothoracic surgery; surgery lasting longer than 4 hours	Hydrocortisone 50 mg IV every 8 hours starting at induction of anesthesia. Continue for 48–72 hours and then quickly taper to outpatient regimen once patient is hemodynamically stable.

ACTH = adrenocorticotropic hormone.

If his peak cortisol level is 20 µg/dL or greater, he does not need supplemental steroids perioperatively. Should he develop hypotension, a random cortisol should be drawn, and he should receive hydrocortisone 50 mg IV followed by fluid resuscitation until his adrenal sufficiency is better

established. An endocrinology consultation would be appropriate at that point for recommendations on further management.

35 THE SKIN AND THE PHYSIOLOGY OF NORMAL WOUND HEALING

Sahil K. Kapur, MD, and Timothy W. King, MD, PhD

The Skin

The skin is composed of epidermis and dermis, which interdigitate to form an irregular contour. The epidermis is primarily of ectodermal origin and is classified as stratified squamous keratinized epithelium. The major cell types found in this layer include keratinocytes, melanocytes, Langerhans cells, and Merkel cells. Regeneration of this layer occurs every 30 days via the mitotic activity of keratinocytes. The epidermis can be subdivided into five layers: stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, and stratum basale.

The stratum corneum is the most superficial layer of the epidermis, containing flattened dead cells (squames) along with keratin filaments. The next layer, the stratum lucidum, contains cells that lack nuclei or organelles and only contain cytoplasm packed with keratin filaments and eleidin. The stratum granulosum consists of nucleated keratinocytes that contain coarse keratohyalin granules associated with tonofilaments. Cells in this layer are arranged in three to five sublayers. The stratum spinosum contains nucleated keratinocytes that have a spiny appearance. Desmosomes associated with tonofilaments connect cells in this layer via intercellular bridges. Keratinocytes in this layer are mitotically active and contain membrane-coating granules. Langerhans cells also reside in this layer. The deepest layer of the epidermis is the stratum basale, which is composed of a single layer of tall, cuboidal, mitotically active keratinocytes along with Merkel cells and melanocytes.

The dermis is subdivided into a papillary layer and a reticular layer. The papillary layer is the superficial layer of the dermis; it is irregular and forms dermal ridges that interdigitate with down-growing epidermal ridges. This layer is composed of type I and type III collagen fibers, anchoring fibrils (collagen type VII), microfibrils (fibrillin), and elastic fibers. Meissner corpuscles and capillary loops are also found in this layer. The deeper reticular layer is far more extensive and contains thick bundles of type I collagen fibers and elastic fibers. This layer contains arteries, veins, lymphatics, pacinian corpuscles, nerves, and sweat glands and their ducts. The epidermis and dermis are separated by the basement membrane. The basement membrane is a thin sheet of fibers made up by the fusion of two layers (basal lamina and reticular lamina). The two layers attach to each other using type VII collagen and fibrillin. The basal lamina in turn consists of two layers: lamina lucida (made up of laminin) and lamina densa (composed largely of type IV collagen). The function of the basement membrane is to anchor down the epidermis to the dermis and to act as a mechanical barrier [see Figure 1].

Financial disclosure information is located at the end of this chapter before the references.

Adult Wound Healing

Adult wound healing can be broadly broken up into an inflammatory phase, a proliferative phase, and a remodeling phase. Each phase has multiple complex processes that are not clearly limited to that phase. So a more accurate description of wound healing would involve discussion of the complex processes as overlapping phases along a continuum.

INFLAMMATORY PHASE

On injury to the skin, the blood vessels constrict and the platelets form a fibrin plug. The degranulation of alpha granules in platelets leads to the release of adhesive proteins such as fibrinogen, fibronectin, thrombospondin, and von Willebrand factor. Fibrinogen, fibronectin, and thrombospondin act as ligands for platelet aggregation, whereas von Willebrand factor facilitates platelet aggregation to fibrillar collagens. The glycoprotein receptor on platelets, GPIIb/IIIa, allows adhesion of platelets to all four adhesive proteins.^{1,2}

The aggregated platelets release chemoattractants for inflammatory cells, factors for local fibroblasts and endothelial cells, and vasoconstrictors. Coagulation and complement cascades are also initiated. After the initial vasoconstriction, there is vasodilatation mediated by bradykinin, which is generated by the Hageman factor in the coagulation cascade.^{3,4} The complement cascade generates the C3a and C5a anaphylatoxins, which directly increased blood vessel permeability, allowing neutrophils and monocytes to enter the wound. C3a and C5a also stimulate the release of histamine and leukotrienes C₄ and D₄ from mast cells, resulting in endothelial cells losing their cell-cell contact, which then leads to increased permeability.

Initial inflammatory cells are neutrophils that predominate in the first 24 to 48 hours. They are primarily responsible for the oxidative burst and play a role in phagocytosing cellular debris, foreign bodies, and bacteria. Neutrophils are attracted to the wound site by a multitude of chemoattractants [see Table 1]. Free-flowing neutrophils in the bloodstream that reach the wound bed adhere to the blood vessel endothelium and transmigrate into the wound bed. Increased neutrophil surface expression of CD11/CD18 and the interaction of these complexes with Lewis factor X are responsible for this adherence.^{5,6} Neutrophils are also recruited to the wound by low-molecular-weight chemotactic factors belonging to the alpha-chemokine family that bear the motif C-X-C. Examples of molecules possessing this C-X-C motif include interleukin-8 (IL-8), growth-related protein (GRO), and melanoma growth-stimulating activity (MGSA).⁷ The neutrophils then degranulate and start phagocytosing foreign bodies and debris.

Once foreign bodies and debris have been removed, the granulocyte activation stimulus ends. If there are sustained

Platelet-activating factor (PAF)	Endothelial cells and activated neutrophils

PDGF = platelet-derived growth factor.

foreign substances, neutrophils continue to be attracted to the wound and continue to inflict significant toxic damage to surrounding tissues. Bacteria and retained foreign substances in wounds provide a surface on which alternate complement pathway proenzymes can be adsorbed. This leads to opsonization of these surfaces with C3b and continual generation of C3a and C5a anaphylatoxins. Consequently, neutrophils continue to be attracted to the area.⁸

In the normal wound healing process, chemoattraction of neutrophils to the wound bed ends once bacteria and foreign substances are removed, but the chemoattraction of monocytes continues. Unlike neutrophil-specific chemoattractants, chemoattractants generally specific to macrophages and lymphocytes belong to the beta-chemokine family and are characterized by the C-C motif [see Table 2]. Table 2 also lists macrophage and lymphocyte chemoattractants that are plasma protein derived, cell derived, extracellular matrix (ECM) derived, and bacteria derived. Chemical modification

of certain factors changes their chemoattractant properties. For example, C5a, a potent anaphylatoxin, attracts both neutrophils and macrophages. This factor, however, gets quickly modified in the wound bed to C5a des Arg, which results in a reduction of its anaphylatoxin properties and neutrophil-attractive properties but maintains its monocyte-attractive properties.

Once monocytes arrive at the wound bed, they are transformed into tissue macrophages. Monocytes bear β_1 integrin receptors to wound matrix fibronectin and not soluble fibronectin. Adherence to the matrix fibronectin induces phenotypical transformation of monocytes to macrophages.^{9,10} The adherence-specific phenotypical change involves selective messenger RNA (mRNA) expression of survival cytokines such as colony-stimulating factor-1 (CSF-1), inflammatory cytokines such as tumor necrosis factor- α (TNF- α), potent fibroblast chemoattractants and mitogens such as platelet-derived growth factor (PDGF), and c-fos and c-jun transactivating factors.^{11,12} mRNA expression of other cytokines is adherence independent and includes expression of transforming growth factor- β (TGF- β), IL-1, human leukocyte antigen-DR (HLA-DR), interferon gamma, transforming growth factor- α (TGF- α), PDGF, insulinlike growth factor-1 (IGF-1), and fibroblast growth factor (FGF).

The tissue débridement process is started by monocytes on arrival. By days 2 and 3, they are the predominant cell type within the wound.¹³ They secrete a multitude of tissue-degrading enzymes, which are similar to those secreted by neutrophils, macrophages, and fibroblasts. Specifically, they degrade collagen by secreting matrix metalloproteinase-1 (MMP-1) and MMP-9. They do not, however, secrete any MMP-3, and the levels of secreted MMP-1 and MMP-9 are

much lower than those secreted by macrophages. Monocytes constitutively secrete tissue inhibitor of matrix metalloproteinase-1 (TIMP-1), which inhibits the function of the above-mentioned metalloproteinases. Unlike macrophages, monocytes degrade elastin by secreting serine and cysteine proteases. As they transform into macrophages, they begin to secrete MMP-3; increase production of MMP-1, MMP-9, elastase, acid hydrolases such as cathepsins and glycosidases; and decrease production of serine/cysteine proteases. They therefore function not only to phagocytose bacteria but also to secrete a multitude of factors to activate endothelial cells, fibroblasts, and keratinocytes. Interestingly, macrophages and monocytes are the only inflammatory cells required for wound healing¹⁴ [see Figure 2].

The fibrin clot in the blood vessel that forms immediately after tissue injury serves to control hemostasis, whereas the fibrin clot within the wound provides the initial provisional matrix for migration of cells into the wound. Clot contains large amounts of fibrin and lesser amounts of fibronectin and vitronectin. Integrin receptors on migrating cells recognize fibrin, fibronectin, and vitronectin within the matrix.^{15,16} Clot lysis on the wound periphery is as tightly regulated as clot formation. Clot progression inhibition and lysis are carried out by local production of prostacyclin, which inhibits platelet aggregation; antithrombin III, which inhibits thrombin; and protein C, which degrades coagulation factors V and VIII. Tissue plasminogen activator (t-PA) and plasmin, which are usually inhibited by fluid phase proteases such as plasminogen activator inhibitor and α_2 -antiplasmin, escape lysis by binding to the fibrin clot.

PROLIFERATIVE PHASE

Fibroplasia

This phase begins with the degradation of the initial platelet-fibrin matrix. Growth factors released by the macrophages and local ECM components increase fibroblast proliferation. By days 3 to 5, fibroblasts are the predominant cell type in noninfected wounds. After proliferation, fibroblasts begin to synthesize and secrete ECM components. The initial platelet-fibrin matrix is replaced by a second provisional fibronectin-hyaluronic acid matrix. This process is complex and involves multiple growth factors that help regulate cellular function via transmembrane integrin receptors. The hyaluronic acid in the new wound matrix

Figure 2 Phenotypic changes during the differentiation of monocytes to macrophages. CSF-1 = colony-stimulating factor-1; MMP-1 = matrix metalloproteinase-1; MMP-9 = matrix metalloproteinase-9; PDGF = platelet-derived growth factor; TNF- α = tumor necrosis factor- α .

facilitates cell migration because it is largely composed of water. Adhesion glycoproteins, which include fibronectin, laminin, and tenascin, facilitate cell migration and attachment. Extracellular components such as glycosaminoglycans (GAGs) and glycoproteins transmit signals intracellularly via integrin receptors on cell membranes. Fibroblasts that populate the wound release hyaluronidase to digest the provisional matrix and allow for larger sulfated GAGs to be deposited. New collagen is deposited by fibroblasts onto the fibronectin and GAG scaffold in a disorganized manner, resulting in scar formation [see Figure 3].

The main types of fibrillar collagens that compose the ECM in skin and scar tissue are types I and III and are present in a 4:1 ratio.¹⁷ About 19 different types of collagen are currently known.¹⁸ Most of these are synthesized by fibroblasts and some by keratinocytes.¹⁹ Coordinated transcription of various genes on fibroblasts, followed by multiple intracellular and extracellular modifications of the translated product, leads to the final collagen fiber.^{2,6,7,12,13,17,20} Tropocollagen is made in the ECM. These molecules laterally aggregate and are covalently cross-linked by the enzyme lysyl oxidase to form collagen fibrils.²¹ The high percentage of proline amino acid residues is the basis of their right-handed triple-helix structure.

Fibroblasts enter the wound by initially penetrating through blood clot, which has large amounts of fibrin and relatively lesser amounts of fibronectin and vitronectin. Fibroblasts bind to fibronectin, vitronectin, and fibrin through integrin receptors. The RGDS (Arg-Gly-Asp-Ser) tetrapeptide within the cell-binding domain of these matrix proteins is critical for binding of integrin receptors. Interaction with fibronectin through the $\alpha_4\beta_1$ integrin receptor induces migration, whereas interaction with the $\alpha_5\beta_1$ receptor retards movement of the fibroblast. PDGF and TGF- β stimulate fibroblasts to migrate. PDGF has a variable effect on fibroblasts based on the ECM environment. When fibroblasts migrate through a fibrin-fibronectin matrix, PDGF stimulates formation of receptors for fibronectin ligands,

whereas when these cells migrate through collagen gels, PDGF stimulates receptors for collagens.

Migration of fibroblasts is influenced by chemotactic, haptotactic, and contact guidance signals. Chemotactic signals cause fibroblasts to extend their lamellipodia in the direction of the signal and release other attachments, thereby allowing the cell to migrate. Haptotactic signals cause movement of fibroblasts relative to a surface adhesion gradient and can be described in the following manner. Fibroblasts randomly extend lamellipodia, each of which compete for cell membrane surface area. The lamellipodium that adheres the most wins, causing the entire fibroblast to migrate in that direction.²⁰ Fibroblasts, presented with a chemotactic signal, migrate faster along fibronectin fibrils rather than across these fibrils. This property is known as contact guidance. As they migrate through the tightly woven ECM, they secrete interstitial collagenases (MMP-1), gelatinases (MMP-2), and stromelysin (MMP-3) to aid in migration. PDGF and TGF- β stimulate the production and secretion of these collagenases.

Once fibroblasts have migrated into the wound, they undergo a phenotypical change and transform from primarily migratory cells to protein-secreting cells. Initially, they produce large quantities of fibronectin, which gives rise to a loose ECM. As the wound matures, their protein expression shifts to TGF- β , resulting in the production of collagen III and collagen I. Once abundant amounts of collagen are produced, the matrix suppresses fibroblast collagen production. In contrast, a fibronectin-rich ECM does not exert a similar suppressive effect.

Contraction

By the second week of wound healing, profibrotic fibroblasts begin to transform their phenotype into a myofibroblast phenotype. They accumulate large quantities of actin-containing microfilaments and present them along the cytoplasmic face of their plasma membranes. They then connect to fibronectin within the ECM using $\alpha_5\beta_1$ integrin receptors and to collagen fibrils using $\alpha_2\beta_1$ and $\alpha_1\beta_1$ receptors. Fibroblasts connect to each other through direct adherens junctions.^{22,23} The collagen bundles connected to fibroblasts within the matrix then form end-to-end contacts with collagen bundles at the wound edges and create covalent cross-linked bonds with collagen bundles within the adjacent dermis. This sets up an interconnected network that can transmit the force of contraction of the myofibroblasts to the periphery. Myofibroblasts are aligned along the contraction lines of wounds to better transmit this contractile force. PDGF isoforms AB and BB, released by platelets and macrophages, stimulate contraction. Interestingly, PDGF-AA released by fibroblasts has no such activity. It is therefore assumed that resident tissue macrophages release a wave of PDGF-BB or AB at the appropriate time to stimulate wound contraction. Open wounds undergo contraction, which leads to reduction in the size of the wound without new tissue formation. Eighty to 90% of wound closure can be carried out by contraction in the abdomen and the perineum²⁴ [see Figure 4].

Neovascularization

Activated macrophages that are attracted to the wound bed release FGF-2, which stimulates the endothelial cells to

Figure 3 Proliferative phase. The platelet-fibrin matrix transforms into the fibronectin-hyaluronan matrix. Clot lysis at the wound periphery is tightly regulated by prostacyclin, antithrombin III, and protein C. Fibroblasts interact with fibronectin, laminin, and tenascin and deposit collagen as they migrate across the fibronectin-hyaluronan matrix. This leads to the transformation of the fibronectin-hyaluronan matrix into the collagen matrix.

Figure 4 Wound contraction. Migratory fibroblasts transform into collagen-producing proliferative fibroblasts and then into myofibroblasts. These myofibroblasts connect to fibronectin and collagen fibrils with the matrix, align themselves along lines of tension, and contract under the influence of PDGF-BB and -AB. PDGF = platelet-derived growth factor.

release plasminogen activator and procollagenase. Plasminogen activator converts plasminogen to plasmin and procollagenase to active collagenase. These help digest the ECM, allowing the endothelial tubes to grow into the tissue. The endothelial cells that form tubes express $\alpha_v\beta_3$ integrin, which facilitates adhesion and migration. As the neovasculation grows into the wound bed, it first deposits its own provisional matrix, containing fibronectin and proteoglycans, and later forms a true basement membrane. FGF-1, FGF-2, and vascular endothelial growth factor (VEGF) stimulate endothelial proliferation and allow for a continual supply of cells as the tubes migrate into and revascularize the wound bed. TGF- β helps induce the correct endothelial cell type for capillary tube formation and helps stimulate fibronectin and proteoglycan synthesis. Whereas VEGF stimulates endothelial cell production and TGF helps induce the correct endothelial cell type, angiopoietin-1 (Ang-1) serves as a ligand that interacts with TIE-2 receptor tyrosine kinase (present on endothelial cells and endothelial progenitor cells) to mediate neovessel maturation. Ang-1-TIE2 interaction stimulates recruitment of periendothelial cells and helps reestablish the basement membrane, thereby enhancing neovessel integrity and allowing them to mature into more complex vascular structures²⁵ [see Figure 5].

Granulation

Granulation tissue is given the name because of its visual appearance. Its formation is stimulated by a high local concentration of growth factors, especially PDGF. Growth factors are present in the blood at a low concentration. Their local concentration is increased initially by the degranulation of platelets, and these high levels are sustained by macrophages. The major growth factor that induces the formation of granulation tissue is PDGF-BB.²⁶ Application of PDGF to a wound bed can increase granulation tissue by 200% compared with controls. Platelets, fibroblasts, and macrophages release endothelium-stimulating factors such as VEGF, which cause increased levels of endothelial cell division and migration.^{26,27} Macrophages that enter the wound produce high quantities of urokinase-related plasminogen activator (u-PA). Whereas tissue plasminogen activator plays an important role in the destruction of a

Figure 5 Neovascularization. Macrophages release FGF-2, which causes endothelial cells to release plasminogen activator and procollagenase, which help in ECM digestion. Endothelial cell proliferation is increased in the presence of FGF-1, FGF-2, and VEGF. TGF- β helps with endothelial cell selection. Ang-1-TIE-2 interaction leads to increased neovascular integrity. Ang-1 = angiopoietin-1; ECM = extracellular matrix; FGF-1 = fibroblast growth factor-1; FGF-2 = fibroblast growth factor-2; TGF- β = transforming growth factor- β ; TIE-2 = tyrosine kinase receptor; VEGF = vascular endothelial growth factor.

fibrin clot, u-PA is highly expressed in the endothelial cells, which are in the early stages of angiogenesis in developing granulation tissue. Regulation of u-PA is dependent on activities of basic fibroblast growth factor (bFGF)/FGF-2, TGF- β , hepatocyte growth factor (HGF also called scatter factor [SF]), and VEGF. bFGF increases u-PA activity and decreases plasminogen activator inhibitor activity, whereas TGF- β has the opposite effect. bFGF and VEGF synergistically increase endothelial plasminogen activator production and angiogenesis.²⁸ HGF/SF have structural homology similar to that of plasminogen and are activated by u-PA. Activated HGF in turn reactivates u-PA, thereby promoting angiogenesis in granulation tissue. These interactions result in the formation of a dense bed of capillary networks with embedded fibroblasts and macrophages, which we call granulation tissue. Wound beds that have sufficient granulation tissue readily accept skin grafts.

Proteoglycans are another class of macromolecule that plays an important role in the development of granulation tissue. After injury, there is a temporal expression of hyaluronan and sulfated GAGs in skin. Hyaluronan is deposited early and reaches its peak in the first few days following injury. It is subsequently replaced by sulfated GAGs, such as decorin, versican, and biglycan. Hyaluronan not only provides a low-impedance environment for the migration

of cells into the wound but also reduces inflammation by inhibiting neutrophil function. Unlike adult wounds, fetal wounds do not show a decrease in the level of hyaluronan. They consequently display decreased inflammation and superior dermal matrix reorganization.

Syndecans are heparin sulfate proteoglycans containing a type I transmembrane core protein that can be modified by heparin sulfate and sometimes chondroitin sulfate chains. They form the major proteoglycans in multiple organs and the vasculature. Intact human epidermis expresses syndecan-1 and -4, which are not seen in intact dermis. After injury, syndecan-1 and -4 expression is induced in the dermis. Syndecan-1 is mainly expressed in endothelial tissue, whereas syndecan-4 is expressed throughout granulation tissue, including fibroblasts and endothelia. This increased expression decreases to baseline levels 7 days following injury. In the epidermis, however, migrating keratinocytes significantly decrease syndecan expression from their baseline levels.

GAG such as chondroitin sulfate and dermatan sulfate also interact with matrix molecules, such as laminin and fibronectin. This interaction leads to decreased cell adhesion, thereby facilitating migration of cells within granulation tissue [see Figure 6].

EPITHELIALIZATION

Reepithelialization of the wound begins within 1 to 2 days of tissue injury. Keratinocytes at the wound edges undergo a significant morphologic change. They retract their intracellular tonotopic filaments, dissolve most intercellular desmosomal connections, form peripheral cytoplasmic actin filaments, and lose apical-basal polarity. New migrating epidermal cells are generated by a dividing layer of basal cells near the wound edge. This layer of basal cells is essential because migrating keratinocytes lose the ability to divide.²⁹ These cells do not terminally differentiate into keratinocytes, witnessed by the fact that they do not have the keratins found in terminally differentiated cells, nor do they contain fillagrin, a matrix protein in which these keratins are embedded. They have keratins that are similar to those found in the basal cells of the epidermis.^{30,31} They are, however, not identical to basal cells because they contain involucrin and transglutaminase, components of

cell walls that are found only in the stratum granulosum of normal epidermis.

If the basement membrane is destroyed, these keratinocytes migrate over a provisional matrix consisting of collagen, fibrin, fibronectin, tenascin, and vitronectin. If the basement membrane is intact, circulating fibronectin, deposited by macrophages, fibroblasts, and migrating keratinocytes, infiltrates the basement membrane. Migrating keratinocytes, in contrast to normal keratinocytes, express large numbers of active integrin receptors for fibronectin, which allows them to migrate over the basement membrane. As the keratinocytes migrate across the wound, they eventually reach areas where the basement membrane is no longer intact and the cells directly contact the underlying matrix. This cell-matrix contact induces production of large amounts of collagenases that help degrade type I and type III fibrillar collagens, which are not normally found in intact basement membranes. These collagenase-producing basal keratinocytes express $\alpha_5\beta_1$ integrin receptors, which allow them to migrate over fibronectin, and $\alpha_2\beta_1/\alpha_1\beta_1$ integrin receptors, which allow them to bind to type I collagen.³² Proinflammatory cytokines such as IL-1 and TNF- α modulate collagenase expression in these cells. Relatively few matrix molecules, mainly collagen I and collagen III, are degraded by collagenases. Other matrix molecules, such as fibronectin, laminin, type IV collagen, and GAGs, contact migrating keratinocytes and need to be degraded as well. Stromelysin-1 and -2 are the major MMPs produced by keratinocytes that perform this task. Stromelysin-2 production is strictly confined to keratinocytes in the epidermis. This is in contrast to stromelysin-1, which is mainly secreted by dermal cells and keratinocytes in chronic wounds.

As the process of reepithelialization continues, keratinocytes and fibroblasts secrete laminin and collagen IV and new basement membrane is laid down in zipperlike fashion.³³ The epidermal cells revert to a normal phenotype and connect to the basement membrane and to the underlying neodermis through hemidesmosome and type VII collagen fibrils, respectively [see Figure 7].

REMODELING PHASE

The ECM that is present in the wound bed begins remodeling from the start of the inflammatory phase. As stated earlier, the initial clot that forms at the site of injury provides an initial provisional matrix composed largely of fibrin and lesser amounts of a multitude of other proteins, including fibronectin, vitronectin, von Willebrand factor, thrombospondin, and other growth factors. Thrombin

Figure 6 Granulation tissue formation. Macrophages release PDGF, which promotes granulation tissue formation, and uPA, which allows matrix digestion and passage of endothelial cells. FGF-2 = fibroblast growth factor-2; HGF = hepatocyte growth factor; PDGF-BB = platelet-derived growth factor isoform BB; TGF- β = transforming growth factor- β ; u-PA = urokinase plasminogen activator; VEGF = vascular endothelial growth factor.

Figure 7 Reepithelialization. Migrating keratinocytes make contact with the fibronectin matrix using integrin receptors. As they migrate along the matrix, they lay down basement membrane components, laminin and collagen IV, and use MMP-1 and MMP-3 to digest collagen to make room for migration. MMP-1 = matrix metalloproteinase-1; MMP3 = matrix metalloproteinase-3.

cleaves off fibrinopeptides A and B from fibrinogen to yield fibrin, which then noncovalently aligns laterally with other similar fibrin monomers to form protofibrils. These aggregate into fibrils and form a fibrin clot. The clot interacts with inactivated platelets via GPIIb/IIIa receptors, causing these platelets to begin binding von Willebrand factor, fibronectin, and vitronectin in addition to fibrin.

The initial degradation of this fibrin clot begins with the formation of t-PA. When tissue injury takes place, t-PA is released from blood vessel disruption and plasma extravasation. This is then activated by tissue kallikrein and factor Xa and begins clot lysis.

As platelets and inflammatory cells release chemoattractants, fibroblasts enter this initial fibrin-bound provisional matrix. They have a higher affinity for fibronectin, which is present in lesser amounts in the initial matrix. As they bind the RGD cell-binding domains on fibronectin fragments, they release MMP-1 (mammalian collagenase) and degrade the initial matrix. However, when they interact with $\alpha_4\beta_1$ integrin recognition sites found on intact fibronectin, they do not release collagenase and continue to migrate into the wound. As stated earlier, fibroblasts initially lay down loose fibronectin, followed by type III and type I collagen. By 3 to 5 weeks, fibroblasts have reached the center of the wound, and by 5 weeks, the matrix has diminished quantities of fibronectin and large quantities of type III and type I collagen. Deposition of type III and type I fibrillar collagens peaks at 7 to 14 days.

Collagen I is initially found only in the deep layers of the granulation tissue. By days 6 to 13, as the tissue goes under degradation and remodeling, collagen 1 is seen in upper layers. By days 13 to 23, the collagen production in the lower layers of granulation tissue is significantly reduced. Even though collagenases are produced largely by migrating keratinocytes, they are not restricted to the epidermis and are produced by dermal cells at important stages of wound repair and remodeling, such as formation and removal of granulation tissue and resolution of scar tissue. Collagen remodeling during transition of granulation tissue to mature scar is a balance between continued collagen synthesis and collagen catabolism. Lysyl oxidase is the major intermolecular collagen cross-linking enzyme and helps decrease collagen degradation and improve wound tensile strength. Degradation of collagen is carried out by a number of collagenase enzymes. The ones that are well studied include MMP-1 (interstitial collagenase), which cleaves collagen types I, II, III, XIII, and X; MMP-2 (gelatinase), which degrades denatured collagens of all types and native type V and XI collagens; and MMP-3 (stromelysin), which cleaves types III, IV, V, VII, and IX; proteoglycans; and glycoproteins.^{34,35} The functions of these molecules are further inhibited by TIMPs.

Various cytokines also play a regulatory role in this process. TGF- β has been shown to be coexpressed with collagen 1 in the early stages of wound healing and is therefore believed to promote its synthesis.³⁶ IL-1 has been shown to modulate expression of collagens I and III in a dose-dependent manner. Low levels of IL-1 stimulate expression of these molecules, whereas high levels of expression have an inhibitory effect.³⁷ IL-4 also promotes expression of

collagen I in wounds. Interferon gamma and TNF- α counter the effects of the above signals.³⁸

This process of deposition and degradation continues for a year after tissue injury and refers to creating and modifying the tissue scaffold as the wound matures. A balance of function between these groups leads to the formation of a stable scar at the site of the wound. The collagen that is present in the scar at the end of the wound healing process is densely packed as opposed to a reticular arrangement in normal skin. Furthermore, the scar lacks hair follicles, sweat glands, and other skin appendages that are found in normal skin.

The scar initially has a red hue because of the dense network of capillaries present in the wound bed. As the scar matures, the capillaries recede, and the final scar is either hypopigmented or hyperpigmented. The tensile strength of the wound rapidly increases from 1 to 8 weeks and correlates with collagen cross-linking. The strength has been shown to increase at a slower pace until about 1 year, with the maximal strength of the wounded tissue reaching 80% of that of normal skin.

REGULATION

Extracellular Matrix

The ECM consists of growth factors in latent forms. On disruption of the ECM in a wound scenario, the growth factors are released and activated at different time points during the wound healing process. These form the focal regulatory points of the repair process.

Transforming Growth Factor- β

This is a profibrotic growth factor that is released from platelets, macrophages, fibroblasts, and keratinocytes. It also acts in an autocrine manner and stimulates its own release. It influences almost every aspect of tissue repair. During the initial stages of wound repair, it acts as a potent chemoattractant for monocytes, lymphocytes, neutrophils, and fibroblasts. Low concentrations (femtomolar) stimulate chemotaxis. This stimulatory effect is lost at higher concentrations of the growth factor. TGF- β , however, plays its major role in stimulating the production of ECM molecules. The fibroblast is initially attracted to the wound bed by low concentrations of TGF- β and is then activated transcriptionally by high concentrations, as are keratinocytes, endothelial cells, and smooth muscle cells. TGF- β increases ECM synthesis by stimulating the production of collagen and elastin GAGs, increasing integrin expression and integrin-mediated cell-ECM interaction, downregulating MMPs, and upregulating TIMPs.^{39,40} This comes at the expense of increasing fibrosis, which, if high enough, could be detrimental to the normal skin healing process. Prolonged expression of TGF- β is found in wounds that have disrupted basement membranes. Some animal experiments have shown that a lack of TGF activity leads to accelerated healing and a low inflammatory response.⁴¹ TGF- β exists in three isoforms. In animals, TGF- β_1 is the main isoform, and there is reduced expression of the others. Human tissue analysis shows increased prevalence of TGF- β_3 in intact human dermis and predominant expression of TGF- β_1 in the region of reepithelialization of healing wounds.

Platelet-Derived Growth Factor

PDGF is released from the alpha granules of platelets as well as from activated macrophages, activated fibroblasts, smooth muscle cells of damaged arteries, thrombin-stimulated endothelial cells, and epidermal keratinocytes. When released initially from platelet alpha granules, it serves as a chemoattractant for neutrophils, macrophages, and fibroblasts to the wound. It stimulates fibroblasts within the wound to synthesize predominantly noncollagenous components of the ECM: fibronectin, hyaluronic acid, other GAGs, and adhesion proteins. It also induces contraction of collagen matrices and collagenase production during the wound remodeling phase.^{42–44} PDGF plays a role in angiogenesis, which is demonstrated by the appearance of PDGF on capillary endothelial cells and microvascular pericytes.⁴⁵ It promotes angiogenesis indirectly by increasing the secretion of endothelial cell growth factors from myofibroblasts. These angiogenic effects are, however, much weaker than those of other proangiogenic growth factors, such as FGF.

The major effect of PDGF is seen in the increased formation of granulation tissue, with PDGF-BB being much more effective than PDGF-AA. Experimental models show that local application of PDGF increases fibroblast and GAG-rich granulation tissue by 200% in 7 days compared with controls.⁴⁶ PDGF-BB application increases wound strength by 150 to 170% and decreases healing time compared with controls.⁴⁷ PDGF does not alter the sequence of wound healing but is known to greatly increase its rate. PDGF is being used in the treatment of diabetic wounds because of the powerful stimulus it provides to induce granulation tissue.

Fibroblast Growth Factor

FGF-1 and FGF-2 are synthesized by monocytes/macrophages, T lymphocytes, vascular endothelial cells, and dermal fibroblasts. They are secreted into the ECM and lie in a dormant form bound to heparin and GAG heparin sulfate, until injury takes place. They have multiple isoforms each with a broad range of biologic functions. FGF-1 (acidic FGF) and FGF-2 (bFGF) are released by endothelial cells, fibroblasts, and macrophages. Both FGF-1 and FGF-2 stimulate angiogenesis, causing endothelial cells to divide and form capillaries. FGF-2 is also found in the basement membrane, where it is present as a storage depot and is released from the heparin components of the basement membrane at sites of injury. It stimulates plasminogen activator and collagenase activity in endothelial cells, thereby causing the breakdown of basement membrane and migration of endothelial cells through the stroma. FGF-2 also stimulates the migration of fibroblasts and then stimulates fibroblasts within granulation tissue to produce collagenases, leading to remodeling of the matrix. Both FGF-1 and FGF-2 act as mitogens for keratinocytes during reepithelialization, although FGF-1 plays a more potent role.⁴⁸

FGF-7, also known as keratinocyte growth factor-1 (KGF-1), is synthesized by stromal cells and differs significantly from other members of the FGF family in that it is a highly specific mitogen for epithelial cells with no mitogenic activity for endothelial cells or fibroblasts. Its synthesis is induced by IL-1, and it acts as a paracrine mediator of epithelial cell proliferation. FGF-10 functions along with FGF-1 and epidermal growth factor to stimulate epithelialization.

Conclusion

Normal wound healing is a complex process that is generally carried out in three highly overlapping stages and under the influence of multiple cytokines, growth factors, and ECM signals. The process is based on the balance of tissue degradation and deposition, which is critically dependent on the successful interaction of multiple factors and processes.

37 MANAGEMENT OF CHRONIC WOUNDS

Lee D. Faucher, MD, FACS, Angela L. Gibson, MD, PhD, and Michael J. Schurr, MD, FACS

Chronic wounds are challenging for both the practitioner and the patient. These wounds often cause pain and can lead to unemployment, social activity disruption, and quality of life issues for the patient. With the world population advancing in age and increasing in body mass index, leading to an increase in the comorbidities of diabetes and venous insufficiency, there has been an increase in the number of patients with chronic wounds.¹

Chronic wounds affect 3 to 6 million patients in the United States, with treatment estimated to cost up to \$25 billion each year.² There was little consensus in the definition or treatment of chronic wounds until the members of the Wound Healing Society established a committee that took on this task.³ After several meetings and public hearings, they published the first set of guidelines and definitions in 1994.⁴ In 2003, the Wound Healing Foundation funded a grant to support the Wound Healing Society in their effort to advance their initial guidelines and develop the best treatment for chronic wounds.⁴ These guidelines, most recently published in 2006, represent the most complete synopsis of the understanding of chronic wound pathophysiology and current treatment recommendations.^{5–8} As a result of the continued research in the field of wound care, the board of directors of the Wound Healing Society and the Wound Healing Foundation established that these guidelines must remain dynamic and that revisions will be made as they become necessary.³

Disease Definition

Chronic wounds are those that have failed to proceed through an orderly and timely reparative process to produce anatomic and functional integrity of the injured site.⁴ Diagnosis and management of chronic wounds often depend on the inciting pathophysiology; therefore, they are traditionally divided into etiologic subtypes. Chronic wounds are rarely seen in individuals who are otherwise healthy and are usually associated with disease states such as diabetes or obesity. Peripheral vascular disease and venous insufficiency can also lead to lower extremity chronic wounds, as can other systemic diseases. The lower extremity ulcer caused by vascular insufficiency or diabetes is the most commonly encountered chronic wound and accounts for 98% of all lower extremity wounds.⁵ Other patient factors, such as malnutrition, immunosuppression, and infection, contribute to poor wound healing. Identification and treatment of these factors are the key to successful management of the chronic wound.⁹

Wound Healing Necessities

OXYGEN

Decreased blood flow in wound tissue limits oxygen delivery and leads to wound hypoxia. In addition to the low tissue

partial pressure of oxygen, decreased blood flow also causes a discrepancy between the delivery of nutrients to the wound and the metabolic demand of the tissue. Cells under hypoxic stress can either adapt to the challenge by increasing the rate of glycolysis and conserving energy or undergo cell death.¹⁰ Mild to moderate tissue hypoxia can be tolerated by tissues with an appropriate adaptive response. Chronic, extreme hypoxia will lead to tissue loss. Associated wound conditions such as infection intensify this cascade and lead to further and more rapid tissue loss and poor wound healing.^{11,12} Simply put, in situations of wound tissue hypoxia, the natural increase in oxygen demand of the injured tissue is further complicated by a decrease in the delivered oxygen. Mitochondrial respiration consumes 90% of oxygen in humans. Cells need oxygen as the final electron acceptor in aerobic metabolism of glucose to generate adenosine triphosphate (ATP), which acts as the fuel for cells needed for wound healing.¹³ A hypermetabolic state occurs in healing tissues, and additional energy is generated from oxidative metabolism, which in turn increases the oxygen demand of the healing tissue.^{14,15} The generated ATP powers tissue repair, and extracellular ATP at the injury site can be used as an additional energy source. ATP can also act as a signal in a wound to release other growth factors, such as epidermal growth factor with an independent downstream signaling mechanism.¹⁶ ATP levels correlate with levels of oxygen in the surrounding tissues and thus stimulate factors important to wound healing, such as those that cause local vasodilation and smooth muscle and endothelial cell proliferation.^{17,18} Therefore, local tissue hypoxia affects the wound at the cellular level directly via diminished production of ATP and downstream reduction in the ATP-induced signaling mechanisms necessary to improve the local wound healing environment.

It is important to realize that wound hypoxia is variable within a wound, ranging from anoxia to mild hypoxia, and that this range may vary in different portions of the wound.^{19,20} The anoxic areas of a wound lead to further injury in the surrounding areas because of inflammation and infection. Although hypoxia stimulates angiogenic factors, an appropriate increase in wound oxygen is often limited, for example, in disease states that affect the ability of oxygen to be delivered to the alveoli and attached to the red blood cell for transport or in the case of limited blood flow associated with peripheral vascular disease juxtaposed to the wound [see Table 1].

Simply increasing the partial pressure of oxygen is not a solution given that the cellular environment needs to maintain oxygen levels within a very narrow range. Damage occurs from excessive oxygen as a result of oxidative damage just as readily as metabolic demise results from insufficient oxygen. Tissues and cells have a set point where there is no signal of diminished or excessive oxygen levels. Lungs and vasculature

have a relatively high set point, and organs such as the liver have a very low set point.²¹ Cells exposed to changes in the partial pressure of oxygen that differs from the normal set point will alter the set point to match the new state. This occurs as an adaptive function of the tissue to adjust its oxygen consumption required to perform its usual function.²² The cell's ability to perform this adaptive response is not completely understood and provides a potential avenue to investigate pharmacologic interventions aimed at stimulating the angiogenic response to augment wound healing.

Chronic intermittent systemic hypoxia is another common life-threatening condition that occurs in many disease states. This condition leads to an increase in production of reactive oxygen species—dependent responses that are linked to a variety of morbidities.²³ Nearly half of all patients with chronic wounds of the lower extremities have been found to suffer from chronic intermittent systemic hypoxia; however, it is not known whether development of the wound is a cause or a result of the hypoxia.²⁴

Despite a variety of causal relationships implicated in the development of chronic wounds, hypoxia is a common etiologic factor. Tumor biology has shown that moderate hypoxia is angiogenic when the condition is acute. The extreme hypoxia seen in many chronic wounds leaves a situation that is incompatible with cellular life or tissue repair. The limitations of a given wound must be analyzed and a strategy developed to address the limitations. Both too much and too little oxygen delivered to a chronic wound may adversely affect the healing process. Ideally, future research focused on investigating the oxygen-sensing pathways will aid the clinician prescribing appropriate oxygen therapy.

NUTRITION

Nutrition deficiencies affect the normal progression through the stages of wound healing by prolonging the inflammatory phase, decreasing fibroblast proliferation, and altering collagen synthesis.²⁵ Malnutrition is also known to decrease wound tensile strength and increase rates of infection. Nutritionally deficient patients experience delayed wound healing and are at significant risk for chronic wounds. Malnutrition is a common admission diagnosis for hospitalized patients. Up to 60% are either malnourished or at risk for malnourishment if subjected to the increased metabolic demands associated with injury, infection, or surgical wound healing. The number of at-risk patients is up to 85% for residents of nursing homes.²⁶ The etiology of malnutrition is most often multifactorial, including poor nutritional intake. Nutritional requirements increase in both acute injury and chronic wounds, resulting in nutritional deficit if not corrected.

Energy is required to maintain and rebuild the body after injury. Glucose is the major fuel source for collagen synthesis and the most efficient fuel source compared with protein and fat. Individual factors contribute to the energy needs, including gender, age, nutrition status, basal metabolic rate, severity of illness or injury, and stage of the healing process.^{25,26} The required calories for optimal wound healing are between 30 and 35 kcal/kg/day. An individual approach is required for every patient as patients with multiple comorbidities may need greater than 40 kcal/kg/day.^{27,28}

Simply increasing caloric intake is not enough as the correct composition of proteins, fats, and carbohydrates must be maintained. Protein is necessary for the synthesis of enzymes involved in wound healing, proliferation of cells and collagen, and the formulation of connective tissue.^{25–27} All stages of wound healing require protein to rebuild damaged tissue. Sufficient amounts of protein must be ingested to maintain an overall body positive nitrogen balance.²⁵ Protein loss occurs through open wounds and is directly related to the size of the wound. Wounds with excessive drainage have an even greater protein loss. The recommendation for protein intake in healthy adults is 0.8 g/kg/day, with this number increasing to 2 g/kg/day in those with large wounds and known nutritional deficits.^{25–27} Measurement of nitrogen balance by subtracting the grams of urine urea nitrogen excreted over a 24-hour period from the grams of protein ingested during the same period of time may be a useful estimate of net protein loss. Protein intake should be adjusted to maintain a positive balance.

Glutamine is the most abundant amino acid in plasma and provides 60% of the free intracellular amino acid supply and 20% of the total circulating amino acid pool.²⁵ Many of the amino acids have been studied for their effects on wound healing; however, glutamine is the only one with evidence to support its use.²⁵ Glutamine is a nitrogen donor for other amino acids, is critical in the synthesis of cell nucleotides, and is essential for gluconeogenesis.²⁵ Supplementing glutamine at a rate of 0.57 g/kg/day has been shown to improve nitrogen balance and enhance immune function after trauma and sepsis.²⁵

Appropriate vitamin intake is also important in patients with chronic wounds. Vitamin A increases the number of macrophages and monocytes in the wound during the inflammatory phase. It then stimulates epithelialization and increases collagen deposition by fibroblasts. Vitamin A is also lost with the stress of illness or injury; therefore, supplementation of 10,000 to 50,000 IU/day can maintain balance and enhance wound healing.^{25,27} Vitamin C is important in the synthesis of collagen connective tissue in wound healing and works to increase fibroblast proliferation, capillary formation, and neutrophil activity. Smoking and alcohol consumption increase the excretion of vitamin C. Those patients with large wounds or suspected deficiency of vitamin C will require up to 2,000 mg/day of oral supplementation of vitamin C to enhance wound healing.^{25,27}

All patients with chronic wounds and hospitalized patients who may be at risk for wound healing or the development of pressure ulcers should undergo a nutritional assessment on admission and after any major change in patient condition. The patient should then be provided with adequate calories with an appropriate balance of protein, carbohydrates, and

fat. Frequent monitoring of nutritional status will also allow for changes to be made as clinical condition dictates.

APPROPRIATE WOUND BED

It is unrealistic to expect a wound to heal if the systemic factors that affect wound healing are not addressed. In addition, wound-specific factors need to be addressed for wound healing to be possible. Examination of a chronic wound will reveal hyperproliferative margins, but this represents an ineffective proliferative area that will not advance to heal the wound.⁹ Microscopic examination of wound bed fibroblasts demonstrates various phenotypes that do not respond to normal stimulatory messages.^{9,29,30} Inflammation caused by various cellular products and cytokines, along with an increase in matrix metalloproteinases and a decrease in matrix metalloproteinase inhibitors, eventually leads to destruction of the extracellular matrix.³⁰ This profound inflammatory state is the main factor leading to delayed wound healing.

Recent scientific advances such as new techniques in tissue culture, the development of recombinant growth factors, and tissue engineering have led to an increase in understanding the science of wound bed preparation. The development of genetically engineered knockout murine models and the use of inducible genes have led to a better understanding of growth factors. Gene array technology has allowed us to understand functional pathways and the interactions of cellular components that play a part in wound healing.^{31,32}

There is also an art to the management of the wound bed in a chronic wound using clinical judgment. The presence of eschar or gangrenous infection mandates surgical débridement, giving the clinician the advantage of assessing the severity and extent of the underlying wound.³³ Sharp débridement is the appropriate initial therapy, but débridement alone may not be enough to maintain sustained healing as chronic wounds accumulate senescent cells, extracellular matrix products, and inflammatory enzymes that need to be continuously removed. The ultimate goal of débridement is to alter the wound bed so that the properties of an acute wound can be brought to a previously chronic wound.³⁴

The technique of nonselective, excisional débridement is the fastest way to débride a wound, but given that it also removes viable tissue, daily surgical débridement may also be detrimental to the healing wound. Other techniques, such as mechanical, autolytic, or chemical débridement, are often used in an attempt to maintain an appropriate wound bed. Mechanical methods of débridement include wet-to-dry dressing changes, hydrotherapy, and irrigation. These techniques are nonselective and may be painful and thus are usually reserved for large wounds or those with an excessive amount of necrotic tissue.³³ Autolytic débridement is facilitated by the use of moisture-retaining dressings that allow the body's own endogenous proteolytic enzymes and phagocytic cells to remove necrotic debris.³⁵ This process may be prolonged but, in theory, is less harmful to viable tissue. Chemical débridement products use enzymes to digest necrotic tissue. Two such enzymatic agents in use in the United States are papain-urea and collagenase. Papain comes from the *Carica papaya* plant and breaks down protein with cytosine residues.³⁴ The added urea alters the structure of the protein to expose the cytosine residues, making papain more effective.³⁶ Because the use of this product can cause pain,

there is another formulation with additional chlorophyllin that may be less painful. Collagenase, derived from *Clostridium histolyticum*, specifically breaks down native collagen but works only in the pH range of 6.0 to 8.0. Collagenase breaks down exposed collagen but not the collagen in intact viable tissue. Its use should be limited to wounds that are relatively free of chronic wound debris and eschar.

For those patients in whom surgical, mechanical, or chemical débridement of the wound bed is not an option because of confounding medical factors, biosurgery may be an option. Larvae of the green bottlefly, *Lucilia sericata*, will digest necrotic material and have bacteriostatic enzymes effective against common pathogens such as methicillin-resistant *Staphylococcus aureus* and β -hemolytic streptococcus.³⁷ If tolerated, wounds can be selectively débrided of necrotic tissue in up to 2 days.³⁸

Koch and colleagues, more than 150 years ago, isolated individual strains of bacteria and developed the pure culture method that is still in use today.³⁹ Clinical microbiologists worked with pure log-phase cultures in nutrient-rich media (planktonic growth) as this system is ideal for bacterial growth. Some believe that this model for the study of bacteria may have limited the development of a thorough understanding of microbial processes.⁴⁰

In chronic bacterial infections, the planktonic phenotype exists only transiently as a minor population.⁴⁰ It is now understood that bacterial populations are polymicrobial, sessile (attached), community-based collections within a self-secreted protective matrix or biofilm. The extracellular polymeric substances that hold bacterial communities together were first described more than 30 years ago and are found throughout nature.⁴¹ One of the fundamental differences that separate acute and chronic wounds is biofilm production. Biofilm adheres to the surfaces of organic and inorganic structures and provides a barrier against both environmental and pathogenic stressors. Additionally, biofilm provides protection from antibiotics up to 1,000 times the concentration that can inhibit growth in planktonic cells.⁴² Biofilm is effective against biocides, shear stress, and the body's own defenses, including phagocytes and macrophages.⁴² When bacteria make the natural transition from individual planktonic cells to a community of cells secreting protective polymers, creating a biofilm tissue, there is also a change in the transcriptional expression of the bacteria creating new cell-to-cell signaling mechanisms that can cross bacterial species, making biofilm a quite formidable opponent for the host.⁴³ Even wounds that are appropriately débrided of all necrotic tissue can still have active infection that limits wound healing as a result of the biofilm bacteria creating a continuous inflammatory state.

The exact method to characterize and detect biofilm in chronic wounds is an active area of research. A recent study detected biofilm-producing bacteria in 80% of all chronic wounds, and only those wounds without detectable biofilm showed signs of healing.⁴⁴ Treatment is difficult as biofilms are resistant to antibiotics⁴⁵ and biocides,⁴⁶ can evade the host immune system,^{47,48} and are impenetrable by many commonly used antibiotics.^{49–52}

The regulation of gene expression by bacteria to alter their phenotype according to the level of bioburden is known as quorum sensing. In chronic wounds, quorum sensing can

lead to the expression of virulence genes, for example, those encoding biofilm production.⁵³ Chronic wound treatment aims to tip the balance in favor of the host defense system with serial débridement to maintain the level of bacteria below quorum. Wound débridement facilitates healing by decreasing the microbial burden and removing nonviable tissue to allow reepithelialization.

Because topical and systemic agents alone are not effective in removal or suppression of biofilm, physical débridement is necessary to disrupt the biofilm. The bacteria must then increase proliferation and synthesis of the biofilm to regenerate and are subsequently most susceptible to antibiotics and biocides during the first 24 to 72 hours of the new growth phase.^{45,46} Débridement can remove the vast majority of bacteria, but it is unrealistic to expect sterilization of the wound as bacteria tend to integrate deep into the tissue and thus remain after débridement to reproduce the protective biofilm.⁵⁴ Frequent disruption of the biofilm forces it to continually reattach to the host, increasing its vulnerability to attack. Therefore, serial débridement must be integrated into the treatment strategy for all chronic wounds.⁵⁵

WOUND MOISTURE

Almost 50 years ago came the realization that maintaining appropriate wound moisture was important to improve the condition of chronic wounds.⁵⁶ This information led to the production of various wound dressings aimed at providing the wound with a moist healing environment, decreasing pain, minimizing odor, and removing excess fluid that retards cellular proliferation and angiogenesis.^{56–58} However, an appropriate amount of wound fluid containing matrix metalloproteinases, growth factors, and cytokines is necessary for wound healing.^{59–61}

An ideal dressing for chronic wounds is one that maintains appropriate wound moisture, absorbs exudate, prevents maceration of healthy tissue, prevents infection, minimally disturbs healing tissue, and is cost-effective. Unfortunately, this product does not exist. The choice of a suitable dressing must take into consideration the current wound conditions and the greatest threats to wound healing, realizing that dressings alone are inadequate to heal chronic wounds.⁶²

Moisture-retentive dressings are typified by their moisture vapor transmission rate less than 840 g/m²/24 hours.⁶³ Hydrocolloid dressings are the most effective moisture-retentive dressings, releasing moisture at a rate of 300 g/m²/24 hours. This is in comparison with cotton gauze, which loses moisture at a rate four times that of hydrocolloid dressings.⁶⁴ An understanding of the moisture properties of a dressing aids the clinician in choosing the appropriate dressing based on the wound characteristics. Wounds draining excessive exudate benefit from the use of dressings that facilitate removal of excessive moisture from the wound bed. A description of multiple dressings highlighting the moisture vapor transmission rate and appropriate uses appears in Table 2.

In addition to maintaining the moisture balance of a wound, a dressing can also function as a delivery vehicle for antimicrobial agents. Two such agents, cadexomer iodine and silver, offer broad-spectrum coverage and have shown efficacy against biofilms.^{65,66} Iodine was first discovered in 1811, but it was not until 1927 that Dr. Sunker Bisey, a Hindu scientist, found it to be useful on wounds, and it has been in use as an antiseptic agent ever since.⁶⁷ Cadexomer iodine is a

Table 2 Properties of Some Types of Wound Dressings

Dressing Type	Moisture Vapor Retention Rate (g/m ² /24 hr)	Properties
Polyurethane film	300–800	No absorptive capacity
Hydrocolloids	< 300	Not for infected or draining wounds Traumatic to wound with removal Risk of contact dermatitis May have offensive odor
Foams	800–5000	For wounds with excessive drainage, not dry Used with compression bandages
Absorptive wound fillers		Can get into tunneling wounds Atraumatic removal Very absorptive Hemostatic properties Nonallergenic Less patient pain
Hydrogels		Will hydrate wound Nonadhesive Minimizes pain Can be used to provide moisture to another dressing
Cotton gauze	1200	For heavily draining wounds Will adhere to viable tissue Useful as a second layer

Data from Seaman S.¹⁹⁰

polysaccharide starch lattice containing 0.9% elemental iodine that is released on exposure to wound exudate.⁶⁸ The antimicrobial activity of this extensively studied dressing can last for days and is safe and effective in reducing the bioburden of chronic wounds.⁶⁹

Silver is another commonly used antiseptic agent that has been in use for many years. Silver nitrate solution was one of the first formulations used extensively on burn wounds.⁷⁰ This led to the formulation of silver sulfadiazine cream, which was easier to use and effective in the treatment of burn wounds.⁷¹ The element silver is inert in its metallic form; however, it ionizes on contact with body fluid, transforming it into an effective antimicrobial agent.⁷² Additionally, silver absorbed by epidermal cells can induce the production of metallothionein, which, in turn, may increase the uptake of copper and zinc. These elements are postulated to promote cell proliferation and tissue repair through an increase in RNA and DNA synthesis.^{72,73}

Silver can be lethal to bacteria even at very low concentrations, thus prompting the development of several sustained-release dressings that deliver high concentrations of ionic silver at rates of 70 to 100 parts per million.^{74,75} Silver is toxic to human keratinocytes at higher concentrations both in vitro and in vivo in randomized, prospective clinical trials.⁷² Newer formulations of silver-containing products release silver into the wound at continuous low concentrations, negating the toxic effects that were previously unrecognized in clinical

practice. A recent meta-analysis found statistically improved wound healing, pain, odor, and exudate reduction with the use of silver-containing dressings.⁷⁶ However, there is a delicate balance between bacterial burden reduction and keratinocyte cytotoxicity. The toxic effects of systemic silver have been examined, and although it has been found in liver, brain, kidney, and bone marrow, no known risk has been identified. Argyria, when silver is absorbed and discolors the skin, is non-life-threatening.⁷⁴ Silver sulfadiazine was once thought to lead to leukopenia when used as a treatment for burns; however, postburn neutropenia is now attributed to the associated burn injury.⁷⁷ Further studies are required to fully understand the complete toxicity profile of silver.

Biologic Adjuncts to Wound Healing

VASCULAR ENDOTHELIAL GROWTH FACTOR

Wounds refractory to the normal healing process and timing may be candidates for growth factor therapy, which can stimulate missing or dysfunctional components of the chronic wound. Vascular endothelial growth factor (VEGF) is an angiogenic growth factor that may promote the healing of hypoxic, chronic wounds attributable to compromised blood delivery. VEGF is strictly investigational at this point in time but warrants discussion. VEGF functions as an endothelial cell mitogen⁷⁸ and a chemotactic agent⁷⁹ and induces vascular permeability.⁸⁰ VEGF is unique in that it affects multiple components of the wound-healing cascade, including angiogenesis, epithelialization, and collagen deposition.⁸¹ This homodimeric glycoprotein exists in five different isoforms varying by amino acid chain lengths. It is produced by a multitude of cells involved in wound healing, including endothelial cells, fibroblasts, smooth muscle cells, platelets, neutrophils, and macrophages. Stimulation of angiogenesis involves a stepwise process of vasodilation, basement membrane degradation, endothelial cell migration, and endothelial cell proliferation.⁸² This is followed by capillary tube formation, anastomosis of parallel capillary sprouts, and, finally, new basement membrane formation, with VEGF playing a part in all of these steps. The formation of granulation tissue, fibrovascular tissue with collagen and blood vessels, is essential to normal wound repair. Angiogenesis is at the heart of this process and begins as early as 3 days after wounding.⁸³ The capillary growth that follows allows a conduit to deliver nutrients and other mediators of the healing response. Inhibition of angiogenesis has been shown to inhibit wound healing.⁸⁴

Platelets are the first cellular component to arrive at the wound bed and, when activated, release VEGF. There is a continued cascade of events that respond to this initial stimulation by VEGF with recruitment of monocytes and macrophages to the wound by the chemotactic effects of VEGF, and these cells in turn release more VEGF to induce expression in keratinocytes and fibroblasts. Hypoxia within the wound bed is a strong stimulus to upregulate the secretion and receptor expression of VEGF in all cell types.⁸⁵ The effects of VEGF on wounds are found immediately after injury. It has a vital role in reducing wound hypoxia and metabolic deficiencies through angiogenesis, with maximal activity exhibited 3 to 7 days after injury. Once the wound is granulated, angiogenesis ceases and endothelial cells undergo

apoptosis, with a resultant decline in vasculature. Endogenous VEGF appears to have little effect in patients with chronic wounds. Initial studies using plasma-directed gene therapy to induce VEGF expression for patients with non-specific limb ischemia,^{86,87} Buerger disease,⁸⁸ and myocardial ischemia⁸⁹ have shown promise, with positive results and minimal complications.

Research investigating the positive effects of VEGF on diabetic ulcers, the prototypical model of impaired wound healing, is also under way. The diabetic wound is complicated by a multitude of factors that are explained later in this chapter, but one of the profound problems leading to a diabetic ulcer is low periwound transcutaneous oxygen pressure. Application of VEGF promotes angiogenesis, chemotaxis, and increased levels of nitric oxide. This results in restoration of endothelial cell function to improve nerve conduction, tissue oxygenation, epithelialization, and collagen deposition.⁸¹ VEGF may prove to be effective in the treatment of chronic wounds with deficiencies of blood delivery as gene therapy with VEGF has been shown to restore impaired angiogenesis found in ischemic limbs in murine animal models.⁹⁰

STEM CELL THERAPY

Stem cells serve as the source for replenishing lost cells necessary for repair and tissue regeneration. Tissue-specific stem cells provide daughter cells to repopulate the injured area through differentiation or by releasing signaling molecules to recruit other cells involved in tissue healing.^{91,92} During the inflammatory phase of wound healing, bone marrow-derived hematopoietic stem cells migrate to the wound site to supply leukocytes and differentiate into dendritic cells via the Notch signaling pathway.⁹³ These dermal mast cell precursors and other hematopoietic populations provide the inflammatory phase with macrophages and mature mast cells. Keratinocytes are derived from epithelial stem cells located within the hair follicle bulge and interfollicular populations that are thought to arrive at the wound via paracrine signaling.⁹⁴

Application of stem cells directly to a healing wound is strictly investigational at this time and has several hurdles to overcome, including cell sourcing and delivery, before the full potential is realized. The use of autologous versus allogeneic stem cells would exclude the potential problem of graft versus host disease. Various strategies for the delivery of autologous mesenchymal and epithelial stem cells, including spraying cells with thrombin on a wound,⁹⁵ intradermal injection,⁹⁴ and implanting hair follicle micrografts,⁹⁶ have been studied, with positive results in all phases of wound healing. An alternative stem cell-related wound healing strategy involves intradermal injection of chemokines to attract bone marrow-derived precursors to accelerate skin regeneration.^{97,98} This treatment showed promise; however, the effect was fleeting.

Ideally, a consistent, sustained, localized delivery method of these diffusible factors is necessary to augment the healing process of the chronic wound. The role for stem cell therapy in the treatment of a chronic wound is promising; however, the method of delivery to the wound, such as intradermal injection, topical delivery, or chemotactic stimulation, needs further investigation.

PLATELET-DERIVED GROWTH FACTOR

Platelet-derived growth factor (PDGF) is a dimeric glycoprotein with five different isoforms normally found in platelets, macrophages, and endothelial cells. It promotes cell mitogenesis, migration, and the synthesis of protein and extracellular matrix components. It also has a significant role in angiogenesis. In 1995, the effectiveness of PDGF in chronic wound healing was evaluated when 118 patients with non-healing, lower extremity ulcers of at least 8 weeks' duration were randomized to receive PDGF in a topical gel applied twice daily at a concentration of 30 µg per gram of gel or placebo.⁹⁹ The percentage of patients who healed in the PDGF group was twice that of the placebo group. Since then, several randomized, prospective, blinded, placebo-controlled studies have demonstrated that repeated, once-daily, topical application of PDGF with an increased concentration of 100 µg/g is safe and stimulates healing of chronic, full-thickness diabetic ulcers of the lower extremity.^{100–103}

SKIN GRAFTS

Autograft and allograft can accelerate the closure of ulcers if applied after revascularization and appropriate wound bed preparation. Even in refractory ulcers, they function as biologic dressings providing a matrix for growth. Extracellular matrix therapy is currently being investigated as it stimulates wound epithelialization, increases angiogenesis, and provides bioactive components to the wound bed.¹⁰⁴

Other Adjuncts to Wound Healing

ULTRASOUND THERAPY

Ultrasound therapy has been studied in pressure and venous ulcers and has its effect on wound healing through both thermal and nonthermal properties. It has been shown to augment the remodeling phase and change the cell permeability to improve the rate of healing.¹⁰⁵ However, there have been no randomized, controlled trials as of yet that prove efficacy.

NEGATIVE PRESSURE WOUND THERAPY

Topical negative pressure wound therapy has proven efficacy in ulcers with multiple etiologies by removal of exudate, reducing edema, increasing wound blood flow, and reducing bacterial counts. Thirteen randomized trials have analyzed negative pressure wound therapy against other conventional dressings on all types of chronic wounds. Although topical negative pressure therapy did not result in earlier complete wound healing, a nearly 10-day improvement in the time needed to prepare for secondary closure was observed.¹⁰⁶

HYPERBARIC OXYGEN

Hyperbaric oxygen improves tissue oxygen in ischemic tissue, enhances the rate of angiogenesis, and increases signal transduction of growth factors to the wound bed. These effects can last up to 4 hours after treatment conclusion, and increased oxygen by itself can diminish anaerobic bacterial counts deep within the wound.¹⁰⁷ For hyperbaric oxygen to be successful, the pretreatment wound should be hypoxic but not anoxic. The transcutaneous oxygen tension must be at least 10 mm Hg and less than 40 mm Hg. Levels measured

after therapy greater than 200 mm Hg suggest successful treatment.¹⁰⁸ The only absolute contraindications to hyperbaric oxygen therapy are untreated pneumothorax, restrictive airway disease, and concomitant chemotherapy. The time should not exceed 2 hours or pressure greater than three atmospheres.

Reimbursement for this therapy is currently approved by the Centers for Medicare and Medicaid Services only as an adjunct for wounds with a diabetic etiology and wounds unresponsive to standard therapy for a period of at least 30 days. There must also be measurable signs of healing within 30 days of treatment initiation for therapy to continue.¹⁰⁹

Arterial Insufficiency Ulcers

DIAGNOSIS

More than 10 million people suffer from peripheral arterial occlusive disease in the United States.¹¹⁰ These patients tend to have multiple organ systems, including the heart, kidney, and skin, that suffer from poor arterial perfusion. This combination of problems leads to significant morbidity and mortality, with a 35% 5-year mortality and a 2% rate of lower extremity amputation.¹¹¹ All patients with lower extremity ulcers should be assessed for peripheral arterial occlusive disease. The ulcer may be the first sign of an arterial disease process, and reduction of overall disease-related morbidity and mortality is best accomplished with early diagnosis and interventions.

It is important to distinguish ulcers caused by venous insufficiency from those caused by arterial disease with a history and clinical vascular examination. Relevant history includes timing of ulcer formation, previous treatments, and history of claudication. Symptoms of rest pain or nighttime waking attributable to lower extremity pain should alert you to a possibly more serious problem of limb-threatening ischemia.

A patient's history can easily lead to the diagnosis of arterial insufficiency as a contributing factor for a chronic wound. Those patients presenting with risk factors associated with atherosclerotic disease (such as smoking, diabetes, hypertension, hypercholesterolemia, advanced age, obesity, and hypothyroidism) are more likely to have arterial ulcers. However, other causes of vascular insufficiency, such as thromboangiitis, vasculitis, Raynaud phenomenon, pyoderma gangrenosum, thalassemia, or sickle cell disease, should be entertained as well.¹¹⁰ It is also important to inquire about symptoms of rest pain as this, along with signs of gangrene, has a much higher risk of limb loss than a nonhealing ulcer alone.¹¹²

The clinical examination should include skin quality and hair presence compared with the other extremity. Quantification of capillary refill and evaluation for dependent rubor, along with palpation of both the dorsalis pedis and the posterior tibialis artery, should follow. A bounding pulse can generally rule out arterial insufficiency as the cause of the ulcer, but performing an ankle/brachial index (ABI) can quantify the information. Any abnormal finding on a pulse examination should signal the necessity to perform an ABI [see Table 3]. The sensitivity of a nondetectable pulse for the diagnosis of peripheral arterial occlusive disease is between 17 and 32%, with a specificity approaching 99%.¹¹³ A dorsalis pedis pulse is absent in 8.1% of healthy individuals, and 2.9%

Table 3 Ankle/Brachial Index (ABI)

Steps to performing an ABI:

1. Record systolic blood pressure in each upper extremity; record the highest number
2. Use Doppler ultrasonography to identify dorsalis pedis or posterior tibial signal on the affected extremity
3. Place the sphygmomanometer just above the ankle and inflate it to a pressure higher than the recorded systolic blood pressure
4. Slowly release the pressure of the sphygmomanometer while listening for the return of signal from the dorsalis pedis or posterior tibial artery; record the value when the signal returns
5. The lower extremity value divided by systolic blood pressure is the ABI

lack a palpable posterior tibialis pulse. Both are absent in less than 2% of healthy individuals.¹¹⁴

Physical examination findings suggestive of arterial insufficiency include cold, pale feet in a warm environment; shiny, taut skin; and a punched-out appearance of the ulcer.¹¹⁵ Quantitative findings suggestive of peripheral arterial occlusive disease include a delay in the capillary refill response,¹¹⁶ ABI less than 0.90,^{110,112,114,116} and transcutaneous oxygen tension value of less than 40 mm Hg.^{9,112} Not all patients with an abnormal ABI will require revascularization, and the sensitivity and specificity of this test are reduced in patients with calcified, incompressible vessels. Transcutaneous oxygen tension is thought to be a more effective marker of clinically significant arterial disease than ABI but is not available in every clinic. A meta-analysis of 615 patients requiring lower extremity amputations found that oxygen tension less than 20 mm Hg provides the most accurate prediction of failure to heal or the need for more proximal amputation.¹¹⁷ Transcutaneous oxygen tension is also helpful in assessing the success of a vascular intervention.

MANAGEMENT

Once the diagnosis of arterial insufficiency has been made, a road map of the suspected large vessel vascular defect must be made. This is most often done through angiography, duplex angiography, magnetic resonance angiography, or contrast-enhanced computed tomographic angiography. Each of these diagnostic tools has its own sensitivity, specificity, and complication profile, which are not discussed here. Surgeon preference and individual technical abilities also play a role in the selection of diagnostic tests. In patients with arterial insufficiency, ulcers, and an identified surgically correctable arterial lesion compromising distal perfusion, revascularization is the intervention that represents the greatest opportunity to affect ulcer healing.¹¹⁶ Revascularization is accomplished through open or endovascular techniques. The effectiveness of the intervention is demonstrated by improvements in ABI and transcutaneous oxygen tension measurements. The natural history of patients with arterial insufficiency ulcers and nonreconstructable vessels is that of disease progression and eventual limb loss. The only available options are revascularization or amputation. Failure to correct the underlying vascular disease will lead to a consistently unsuccessful outcome.

TREATMENT

About 20% of patients with peripheral arterial occlusive disease will require revascularization surgery. Open lower extremity infrapopliteal bypass surgery has a 5-year patency rate of about 70% and a 1-year amputation rate of 2%.^{118,119} Infringuinal bypass does not fare as well, with a 57% 5-year primary patency rate and an overall 63% 5-year patency with secondary interventions to salvage the graft. Even with graft failure, 5-year limb salvage rates are 80% in both groups.^{118–120} Today, endovascular interventions are often the first line of treatment of this disease, but long-term patency and limb salvage rates are not yet available.

Although revascularization is the primary step in treating a patient with an arterial insufficiency ulcer, it does not guarantee sufficient delivery of oxygen and nutrients to the wound bed to facilitate healing. A patient's comorbidities require thoughtful consideration when offering any surgical intervention, and a careful risk/benefit analysis of all options must occur with every patient.

Wound Débridement

As stated earlier, initial care of the ulcer itself begins with débridement of the wound bed. If dry eschar covers the ulcer, all débridement should wait until revascularization has occurred because the eschar functions as a biologic dressing.¹²¹ Signs of local or systemic sepsis necessitate débridement prior to revascularization. After débridement, the appropriate wound environment must be maintained to optimize healing, including adequate intravascular volume to augment distal perfusion. Stressors such as pain or cold must be avoided as this increase in sympathetic tone will reduce distal perfusion. Smoking cessation is an absolute necessity in patients with vascular insufficiency ulcers secondary to peripheral arterial occlusive disease as continued smoking leads to vasoconstriction, causing further large vessel occlusive injury and diminished peripheral oxygenation.¹²²

Dressing and Adjuvant Therapies

In those patients who are not candidates for surgical or endovascular treatment of their peripheral arterial occlusive disease, identifying the correct dressing is vital to wound healing. A combination of a dressing and adjuvant therapy serves to débride the wound, maintain adequate moisture, and provide bacterial control. There is no evidence to suggest the superiority of any one dressing; however, the choice of dressings is aided by the aforementioned principles. Additionally, a cost-effective, once-daily dressing choice is suggested. Moist saline gauze dressings are often the most cost-effective dressing but can lead to increased patient discomfort, inappropriate débridement of viable tissue, and increased frequency of dressing changes.¹⁰⁴

Adjuvant therapies cannot replace revascularization but may be useful when revascularization is contraindicated, is unsuccessful, or does not result in the expected ulcer healing. There is a paucity of data on the use of adjuvant therapies to heal arterial insufficiency ulcers, but the initial results are promising. Direct local and spinal cord electrical stimulation have shown effectiveness in animal studies and case series, but randomized trials are lacking from the literature.^{105,123} Spinal cord stimulation has been shown to reduce pain associated with limb ischemia and in one randomized trial of

120 patients was shown to improve 2-year limb survival.¹²⁴ Topical negative pressure wound therapy is effective in ulcers with multiple etiologies as previously mentioned, but its role as an adjunctive therapy in vascular ulcers is not known. In patients in whom revascularization is not possible or the ulcer is nonhealing despite revascularization, hyperbaric oxygen therapy is also a consideration.

PREVENTION

Patients who present with arterial insufficiency ulcers as a result of peripheral arterial occlusive disease have a 10-year mortality risk approaching 60%, and this risk increases with age and the severity of the arterial disease. Management of the underlying disease not only helps prevent future ulcer occurrence but also reduces overall mortality. Smoking cessation, glucose control, and reduction of hypercholesterolemia and hypertension will decrease the risk of ulcer recurrence and cardiovascular complications such as myocardial infarction and stroke.¹²⁵ Most arterial insufficiency ulcers present when peripheral arterial occlusive disease is in its late stages; therefore, the best prevention occurs with early recognition of the signs and symptoms. Intermittent claudication is the hallmark sign of peripheral arterial occlusive disease, yet it presents in only one third of patients, with only a minority of those patients progressing to arterial ulceration.

Care providers must recognize the early warning signs and symptoms [see Table 4] of arterial disease to have a significant impact on ulcer incidence. It is also important to perform an appropriate peripheral vascular examination when patients present with a medical history that places them at significant risk [see Table 5]. When the history or one of these signs is identified, appropriate physical examination and diagnostic

studies can then confirm the presence of the disease. If immediate intervention is deemed unnecessary, the patient must be educated about the future morbidity and mortality this diagnosis carries and appropriate follow-up must be arranged. Reduction in ABI of 0.15 is significant, and referral to a peripheral vascular specialist should be strongly considered as this patient is at even greater risk for complications. Those patients who require revascularization for an arterial ulcer have a 20% risk of requiring contralateral revascularization for ulceration.¹²⁶ An increase in blood viscosity is a poor prognostic factor for those with peripheral arterial occlusive disease, and the use of antiplatelet therapy decreases the overall incidence of cardiovascular death.^{127,128} A randomized, controlled trial found that clopidogrel reduced the incidence of cardiovascular death by 3.7% and that aspirin reduced it by 4.9%.¹²⁷ In a more recent study with over 15,000 patients, double-antiplatelet therapy failed to show further reduction in mortality or ulcer incidence, and treatment was complicated by increased ulcer bleeding. Single-agent antiplatelet therapy is recommended for all patients with peripheral arterial occlusive disease.¹²⁸

Arterial insufficiency ulcers can begin as a result of trauma to an at-risk limb. Appropriate foot protection that is soft and conforming and fits properly will reduce trauma and is especially important for those patients with diminished sensation as they have delayed recognition of an injury. Extreme caution during toenail trimming is suggested for all patients, especially those with associated diabetes mellitus, as trauma to the surrounding tissue during nail clipping may evolve into ulceration. In those patients with an absent pulse and significant neuropathy, a podiatrist or other trained specialist should perform this procedure.¹²⁵

Despite all of this information, early revascularization of those patients without active ulceration is not recommended as the risk/benefit profile does not favor ulcer prevention. With the speed at which endovascular treatments are progressing, and the morbidity of the procedure diminishing, a formal analysis of the data will be necessary to examine when the risk/benefit profile suggests early intervention. Until then, lifestyle modifications remain the most important preventive measure.

Pressure Ulcer

Pressure ulcers affect up to 3 million people in the United States, with an increased prevalence in the elderly, the acutely ill, and those with spinal cord injuries.¹²⁹ A pressure ulcer is simply caused by a lack of blood flow to a section of dermal tissue. When pressure is applied over susceptible tissue, such as the skin over a bony prominence, dermal blood flow is impeded and necrosis develops as a result of tissue hypoxia. Conditions that lead to immobility, altered sensation, reduced tissue perfusion, or hypoxia greatly increase this risk. About 95% of all pressure ulcers occur on the lower portion of the body, with 36% on the sacrum and 30% at the heel.¹³⁰ Both hospital and nonhospital care facilities must report the incidence of pressure ulcer in patients under their care as a marker of quality care. There is a movement toward withholding payments if the pressure ulcer rate is above a set standard; however, this is a controversial area because not all pressure ulcers are avoidable.¹³¹

Table 4 Signs and Symptoms of Peripheral Arterial Occlusive Disease

Signs
Loss of hair
Shiny or dry skin
Dry, black toe
Devitalized soft tissue with dry crust
Thickened toe nails
Deep purple skin when dependent
Cool skin
Symptoms
Decreased walking distance
Exertional leg pain
Numbness or leg fatigue while walking
Nocturnal foot pain
Foot numbness at rest
Leg wounds heal more slowly

Table 5 Risk Factors for Peripheral Arterial Occlusive Disease

Age greater than 75
Known coronary artery disease
Known cerebrovascular disease
Smokers
Diabetes mellitus
Hyperlipidemia
Dialysis-dependent renal failure
Hyperhomocysteinemia
Elevated C-reactive protein

TREATMENT

Pressure ulcers are exceedingly resistant to any known medical therapy and fail to proceed through the normal healing process, as in acute wound healing. As few as 13% of pressure ulcers that develop in acute hospital settings heal within 14 days.¹³² The healing rate of any pressure ulcer is dependent on the stage of the ulcer at diagnosis. [see Table 6]. Stage III ulcers have healing rates of 60% at 6 months, but many require more than 1 year.¹³³

Assessing Severity

The most common staging is derived from the original Shea scale and is recommended by the National Pressure Ulcer Advisory Panel Task Force and Omnibus Reconciliation Act.¹³⁴ The staging consists of categories I to IV, defined by visual characteristics and the depth of the wound. Additionally, there is an unstageable category that denotes that further débridement is necessary to categorize the ulcer. This staging system has several limitations as there is an inability to distinguish progression between stages. Furthermore, not every pressure ulcer progresses through all the stages; for example, there can be significant damage to the deep tissues with only minimal skin changes.

Pressure Relief and Shear Reduction

Healing cannot occur unless pressure is removed from the ulcer. Six randomized, controlled trials with air-fluidized beds suggested improved healing rates when compared with low-air loss beds, and one trial showed improved healing in low-air loss beds compared with foam overlay.^{135–140} However, there is no definitive evidence that one pressure-relieving device is superior to another. Frequent turning and repositioning are the current and most popular method to avoid pressure and shear. Although ideal, it is not always possible to implement this because of patient comorbidities.

Wound Therapy

The principles of wound bed preparation and dressings discussed earlier in this chapter also apply to pressure ulcers. All pressure ulcers require débridement, and, currently, no data favor one form of débridement over another. Hydrocolloid dressings have been shown to significantly improve pressure ulcer healing when compared with dry dressings.¹⁴¹ Dressing choices for pressure ulcers are complicated by the location of the ulcer on the body. Dressings should not add

increased pressure to surrounding viable tissues or create further tissue injury. Difficulties in dressing adherence occur with the presence of ulcers over joints. Loss of the occlusive edge of the dressing will diminish the benefit of moisture retention. Given the inherent difficulty with dressing placement in those with pressure ulcers, topical negative pressure dressings are commonplace. When there is clinical evidence of infection, topical or systemic antibiotics are required. Commonly used topical antimicrobial agents include silver sulfadiazine cream, combination antimicrobial ointments, and solutions of 5% mafenide acetate. Systemic antibiotic therapy should be reserved for those patients in whom the infection has spread beyond the wound or into the bloodstream.

Surgical Treatment

Infection plays a major role in the decision to operate on patients with pressure ulcers, with the success of wound closure maximized when the ulcer is free of local and distant infection. After successful infection control, débridement, and appropriate pressure relief, the wound should show signs of contracture and secondary wound closure within 2 weeks. If these signs do not occur, a quantitative anaerobic and aerobic bacterial wound tissue culture should be obtained to diagnose the possible offending bacteria. Levels greater than 1×10^6 colony-forming units per gram of tissue will impede secondary healing and lead to failure of surgical closure.¹⁴² Topical antimicrobial treatment is recommended in this situation because systemic antibiotics are not effectively delivered to a granulating wound.¹⁴²

Primary closure is an option in patients with pressure ulcers; the efficacy is high in the short term but significantly reduced in the long term, even in younger patients.¹⁴³ About half of the patients will have ulcer recurrence in the same area and 70% will develop a separate ulcer within 6 months.¹⁴⁴ In those patients with stage III or greater ulcers, a myocutaneous flap is the recommended operative treatment. However, postoperative complications occur in 40% of patients undergoing flap procedure and 80% develop ulcer recurrence or new ulcer within 1 year.¹⁴⁵ Much lower rates of limb salvage and higher complication rates are observed in patients with heel ulceration plus end-stage renal disease; therefore, these patients may consider amputation as their primary surgical option even in the presence of a palpable foot pulse.¹¹²

Complications

The presence of pressure ulcers carries a significant mortality in both acute and long-term care settings. A 67% mortality risk is present for patients with pressure ulcers compared with 15% mortality in the same at-risk group of patients without a pressure ulcer. The risk of death is tripled if the pressure ulcer develops within 6 weeks of hospitalization. In long-term care settings, the risk is even more staggering, with a 92% mortality when a pressure ulcer develops within 6 months of admission compared with 4% mortality in those patients who do not develop a pressure ulcer. It is unknown how this correlates with mortality, although the ulcer severity does not correlate with the risk of death. The assumption remains that pressure ulcers develop in patients with associated comorbidities and contributes to the mortality risk. With this knowledge, pressure ulcers may stimulate end-of-life discussions given the inherent caregiving burden.

Table 6 Stages of Pressure Ulcer

Stage	Clinical Findings
I	Nonblanchable erythema Intact skin
II	Injury extends into dermis Presents clinically as an abrasion, blister, or shallow ulcer
III	Full-thickness skin loss Extends down to fascia Deep crater Surrounding tissue may be undermined
IV	Damage to muscle, bone, and supporting structures Frequent undermining and sinus tracts

Osteomyelitis is a frequent complication of pressure ulcers. Plain radiographs are not sufficient to confirm the diagnosis as it is difficult to differentiate between pressure changes to the bone and osteomyelitis.¹⁴⁶ Radionuclide studies are sensitive but have a 41% false positive rate.¹⁴⁷ Computed tomography is also a specific test, but the sensitivity is only 10%.¹⁴⁸ Bone biopsy is the best single test, with a sensitivity of 73% and a specificity of 96%.¹⁴⁹ Sepsis originating from the pressure ulcer is associated with significant mortality and most often requires surgical débridement to gain control of the bacteremia.

Overall, there is no gold standard for the treatment of pressure ulcers. As with all chronic wounds, control of all comorbidities, optimization of nutrition, and prevention of further skin injury are the best ways to begin treating this complex problem.

PREVENTION

The risk of pressure ulcer is complex and multifactorial. These risks are best identified immediately on admission to a health care facility by pressure ulcer risk screening performed by a qualified professional. The best practice process continues with a pressure ulcer risk assessment, formulation of a pressure ulcer prevention care plan, and implementation of the plan with frequent reassessment.

The Braden scale is the most extensively studied tool and consists of six scored parameters.¹⁵⁰ A higher score implies a lower risk of pressure ulcer development [see Table 7]. Reliable predictive ability of the Braden scale has yet to be shown, and it has inadequate performance outside the acute hospital setting. Further effort is needed in this area to identify those patients at risk as a scoring system with a poor positive predictive value will result in implementation of unnecessary and expensive preventive treatment.

Venous Ulcer

DIAGNOSIS

Venous ulcers are the most prevalent cause of chronic lower extremity ulcerations. The diagnosis begins with a detailed examination of the wound characteristics. Chronic venous ulcers of the lower extremity are shallow wounds, rarely involving muscle, fascia, or bone, located in the gaiter area with a surrounding hyperpigmentation. The pathophysiology of the venous ulcer is related to venous insufficiency leading to venous hypertension, which ultimately results

in ulceration. The lower extremity venous system includes the deep veins below the fascia that drain the muscles and the superficial veins above the fascia draining the cutaneous tissue. These systems are connected by the perforating venous system. Various factors are thought to contribute to formation of chronic venous ulceration through venous insufficiency from failure of the venous calf muscle pump, immobility, and valve dysfunction.

A correct diagnosis is paramount to establishing an appropriate treatment regimen for lower extremity venous ulcers. Treatment is ideally formulated with the underlying disease process in mind. According to the guidelines established by the Wound Healing Society, the presence of coexisting diseases such as arterial pathology or distinct entities such as malignancy, collagen vascular disease, or the dermal manifestation of systemic diseases such as sickle cell anemia, leukemia, immunosuppression, inflammatory bowel diseases, or systemic fungal or mycobacterial infections must be identified.^{8,151} Alternative etiologies of chronic lower extremity ulcerations should be entertained and excluded by biopsy if needed, especially if prolonged treatment has not resulted in ulcer improvement. Diagnosis of venous ulcers is accomplished with the aid of classification systems, identification of associated risk factors, and diagnostic imaging.

Various classifications tools have been developed for clinical and research use. The CEAP (clinical severity, etiology, anatomy, pathophysiology) classification is a well-known system that was initially developed in 1994 and revised in 2004.¹⁵² The CEAP is a descriptive classification of chronic venous disorders, aiding in diagnosis and communication of wound management between health care providers, as well as in documentation of clinical research involving chronic venous disorders [see Table 8]. Moving beyond classification, the venous clinical severity score (VCSS) is a dynamic measure that assesses outcomes of treatment. The Venous Severity Scoring system encompasses the CEAP classification and the VCSS to allow for dynamic descriptive characterization of venous ulcers to improve the evaluation of treatment.

A careful assessment of the risk factors associated with venous ulcers aids in developing a diagnosis. Immobility, obesity, lower extremity trauma, advanced age, the presence of varicose veins, especially in pregnancy, and a history of phlebitis are associated with an increased risk of venous ulcerations.¹⁵³ Hypercoagulable risk factors such as elevated factor VIII, von Willebrand factor, D-dimer, the presence of

Table 7 The Braden Scale

Examination of Ulcer	Value				Score
	1	2	3	4

lupus anticoagulant, and previous deep vein thromboses are associated with venous ulcers.^{154,155}

Methods to evaluate abnormalities in the veins include physical examination, handheld Doppler ultrasonography, color duplex ultrasonography, phlebography, and venography. Measurement of arterial insufficiency using ABI [see Table 3], transcutaneous oxygen tension, or magnetic resonance angiography can exclude the presence of arterial disease as an etiology. Phlebography was previously the gold standard for initial diagnostic evaluation; however, it is invasive and costly. Color duplex ultrasound scanning has replaced phlebography in most cases.¹⁵⁶ It provides anatomic and physiologic assessment of venous ulcers in a noninvasive method for confirmation of surgically correctable abnormal venous function. Use of color duplex imaging is essential to guide wound management when visual evidence of venous insufficiency such as varicosities is absent.¹⁵⁷ Once the diagnosis of venous ulcer is obtained, formulation of a directed management plan and prevention of ulcer recurrence are possible.

MANAGEMENT

Management goals include ulcer healing, symptom management to improve quality of life, prevention of ulcer recurrence, and edema improvement. Toward these goals, venous ulcers benefit from nonoperative and operative interventions such as compression dressings and venous surgery, as well as leg elevation, exercise, optimization of nutrition, and tissue perfusion. The extended health care team required for the comprehensive care of chronic wounds may include the patient's primary care provider, general surgeon, plastic surgeon, vascular surgeon, wound care nurse, and

nutritionist. Communication between all health care team members is essential for successful coordination of care.

TREATMENT

The treatment of chronic venous ulcers is multimodal and includes vigilant wound care, compression, and surgery. A chronic wound represents a delicate balance between host defense and infection. Débridement serves to tip the scale toward host defense by decreasing the microbial bioburden. In a retrospective review of two randomized, controlled trials, venous leg ulcers with serial surgical débridements at clinic visits were shown to have significantly higher median wound surface area reduction and higher rates of closure compared with less frequent débridement.¹⁵⁸ Nonsurgical methods of wound débridement, such as collagenase, autolysis, fibrinolysis, and wet-to-dry dressings, have also been used.¹⁵⁹

An ongoing assessment of wound healing is absolutely essential to evaluate if the current line of therapy is effective. This includes visual inspection of the wound with documentation of wound measurements, exudates, and condition of wound base and periwound tissue, as well as signs of infection. The bacterial relationship with a chronic wound is on a continuum from colonization to infection. Colonization is defined as replication of bacteria without tissue injury. All colonized wounds are at risk for infection, at which point the replicating bacteria cause destruction of the tissue. In addition to wound débridement to decrease bioburden, topical antimicrobials in the form of ointments, creams, or dressings may be used as an adjunct in the treatment of chronic venous ulcers.¹⁶⁰ Currently, the use of systemic antibiotics for chronic venous ulcer healing is not recommended except in the setting of acute cellulitis or osteomyelitis.^{161,162}

Infection can be a clinical diagnosis based on the appearance of the wound and should be considered if no progression in wound healing is observed after 2 weeks of débridement and initiation of wound therapy. Quantitative cultures can aid in the determination of subclinical wound infection. A wound biopsy has been the gold standard for quantification of wound infection; however, a prospective study comparing quantitative swab culture and biopsy in chronic wounds demonstrated that swab cultures were as effective as biopsy at predicting healing, noting that the presence of four or more bacterial genera in the wound was predictive of a nonhealing ulcer.¹⁶³ Previous reports showed that a level of bioburden greater than 10⁵ is indicative of an infected wound; however, Davies and colleagues demonstrated a 7-log difference in bacterial burden in a group of clinically noninfected wounds, suggesting that the number of bacteria in a chronic wound may be less important than in acute wounds.^{163,164}

Wound dressings provide multiple roles, including débridement, protection, and moisture control, as previously mentioned. Wound healing is supported in a moist wound environment; however, excessive moisture can cause further wound breakdown. Various dressings, including low-adherence dressings, hydrocolloids, foams, alginates, and hydrogel dressings, have been compared in randomized, controlled trials, although there is no strong evidence pointing toward one dressing that is superior.⁶² Factors such as availability, cost, ease of application, and comfort can help determine which dressing should be chosen. Most often, these dressings are used in combination with compression systems. Compression bandages act to combat the venous

hypertension that results in ulcerations. A multitude of compression systems are in use for chronic lower extremity ulcers. Studies have shown that elasticity in a compression system with multiple components is superior to that in a single-component system or no compression at all.¹⁶⁵ Venoactive agents such as pentoxifylline and micronized purified flavonoid fraction (Daflon) have shown promise in meta-analyses as systemic adjuncts to compression in venous leg ulcers.^{166,167}

Surgical management of venous ulcer disease attempts to decrease ambulatory venous hypertension by preventing abnormal transmission of pressure from deep to superficial veins and is reserved for patients with moderate to severe chronic venous insufficiency. Incompetence of the superficial venous system can be treated with ablation of saphenous vein reflux, saphenous vein ligation and stripping, stab avulsions or phlebectomy of varicosities, and endovenous laser therapy or radiofrequency ablation of the saphenous vein. Incompetent perforating veins are interrupted with techniques such as stab avulsions, open perforator interruption, ultrasound-guided sclerotherapy, laser or radiofrequency ablation, and subfascial endoscopic perforator surgery. Deep venous reflux attributable to incompetent valves can be corrected with internal or external valvuloplasty, although these procedures are less frequently performed. A randomized, controlled trial comparing venous surgery plus compression versus compression alone found that 12-month ulcer recurrence rates were reduced when venous surgery was performed in patients with superficial venous reflux and mixed superficial and deep venous reflux.¹⁶⁸

Autograft coverage of venous leg ulcers provides good initial healing; nevertheless, the persistence of the underlying venous insufficiency leads to high recurrence rates of the ulcers.¹⁶⁹ Multiple studies have assessed allogeneic cultured skin versus compression for healing chronic venous leg ulcers; unfortunately, the findings do not address long-term results more than 6 months postprocedure.^{170–172} If the underlying venous insufficiency is corrected, chronic venous ulcers may be grafted with autologous or allogeneic tissue to assist in more rapid wound closure. Topical negative pressure dressings may also prove advantageous prior to skin grafting to prepare the wound bed, remove excess fluid from tissue, and facilitate graft take.¹⁷³ Nonresponse to treatment as evidenced by a lack of progress in wound healing or an increase in the size of the wound should alert the provider to reassess the type of treatment to date, entertain an alternative diagnosis, determine if infection is present, and assess compliance with treatment.

PREVENTION

Prevention of chronic venous ulcers would save significant health care dollars and morbidity. Interventions focused on treating the risk factors of chronic venous ulcers may prevent the formation of the ulcers or their recurrence. Deep vein thrombosis is one risk factor associated with chronic venous ulcerations. Long-term compression has been shown to reduce postthrombotic sequelae.¹⁷⁴ In those patients with chronic venous insufficiency, a 6-month structured program of calf exercises was shown to improve calf function, which may translate into prevention of ulceration in those at risk.¹⁷⁵ Venous surgery, if performed in the at-risk populations who have signs of venous insufficiency, may also prevent the occurrence of chronic venous ulcers.

Diabetic Ulcers

Diabetes mellitus is the leading cause of nontraumatic lower extremity amputation in the United States and affects up to 15% of all diabetics in their lifetime.¹⁷⁶ Diabetic foot ulcers preceded 85% of these nontraumatic lower extremity amputations.¹⁷⁷ Diagnosis of diabetic ulcers requires an understanding of the factors that lead to the tissue damage. Diabetic neuropathy and peripheral vascular disease, alone or in combination, can lead to tissue destruction or prevent healing of acutely injured tissue and are considered major risk factors associated with diabetic ulcers.

DIAGNOSIS

To understand the nature of the wound, a careful history and physical examination, including history of previous ulcers, course of healing, trauma to the extremity, presence of peripheral vascular disease and/or neuropathy, and history of revascularization, are important pieces of information to gather in formulating a plan of care. Diabetic neuropathy results in decreased sensation and function loss as a result of foot deformities. There are multiple tools in use for the assessment of diabetic neuropathy; however, the most sensitive prediction test for ulceration is the neuropathy disability score to quantify the severity of diabetic neuropathy based on the examination of tendon reflexes and sensory modalities and the Semmes-Weinstein filaments (10-gauge SWF) examination¹⁷⁸ [see Table 9]. Deformities of the diabetic foot cause abnormal pressures, especially on the plantar surface, and can lead to ulceration when normal sensation of increased pressure is disturbed as a result of neuropathy.¹⁷⁹

The association of peripheral vascular disease warrants a detailed examination of the vascular status when confronted with a chronic ulcer in the diabetic patient. Noncompressible vessels in a diabetic patient may lead to a falsely elevated ABI, rendering this standard test for the presence of peripheral vascular disease inaccurate.^{180,181} ABI and pulse volume recordings identify problems with the macrovasculature. Alternative methods to diagnose peripheral microvascular disease must be pursued. Transcutaneous oxygen tension is one such test that looks at the microcirculation and skin perfusion, which is of great importance in the diabetic patient with nonhealing ulcers and apparently “normal” ABIs.¹⁸¹ Digital calcification is rarely encountered compared with

Table 9 Neuropathy Disability Score

Neuropathy Disability Score			
Exam	Score	Right	Left
Vibration perception threshold on great toe	Normal = 0 Abnormal = 1		
Temperature perception on dorsum of foot			
Pin-prick on dorsum of great toe (sharp vs not sharp)			
Achilles reflex	Normal = 0 Minimal = 1 Absent = 2		
	Total score		

lower extremity calcifications in ABI measurements; therefore, the toe/brachial index (normal > 0.65) can be used as a surrogate for the ABI.¹⁸¹ Another symptom common in peripheral vasculature disease, claudication, may be masked by the decreased sensation associated with diabetic neuropathy, further complicating the clinical evaluation of a diabetic patient with ulcer disease.

TREATMENT

Ulcers that develop as a result of high pressure on insensate areas of the foot need offloading as the first line of treatment. Acceptable methods of offloading include crutches, walkers, wheelchairs, custom shoes, standard shoes with modifications, and total-contact protective casts.

The wound bed requires preparation to optimize healing potential, as has been previously described. All necrotic and devitalized tissue requires removal by surgical, mechanical, enzymatic, or biologic means. The aim is to convert the wound from a chronic wound to an acute wound. The wound must be properly débrided, be in bacterial balance, and contain appropriate moisture. Wound cares should occur daily, including cleaning with a nontoxic solution followed by appropriate dressing placement that conforms to previously described principles. Simple soap and water provide the most cost-effective and most readily available agents for wound care. Frequent follow-up is recommended to document changes in the wound and evaluation of offloading and wound care effectiveness. Success of treatment is demonstrated by at least a 40% reduction in ulcer size after 4 weeks of appropriate therapy.¹⁸²

Any wound that has been appropriately débrided, offloaded, and subjected to appropriate wound care but has failed to progress in 2 weeks should undergo quantitative culture for suspected infection. Topical antimicrobial agents should be used in cases where there is no evidence of systemic infection as previously noted.¹⁴² In the acute diabetic wound with signs of local infection, systemic antibiotics are appropriate. The most frequent offending organism is aerobic gram-positive cocci, but infection can be attributable to any spectrum of bacteria. It is standard practice to initiate broad-spectrum antibiotic coverage after obtaining wound cultures. The spectrum of antibiotic therapy is narrowed once sensitivities from the wound cultures are available.¹⁸³

Bone underlying a diabetic ulcer is often infected as a result of direct extension from the ulcer. Although bone biopsy is the most effective way to make this diagnosis, x-rays, magnetic resonance imaging, and nuclear medicine scans can also be used. Infected bone should also be débrided followed by up to 4 weeks of culture-specific antibiotics. If the patient's

comorbidities preclude intraoperative débridement, osteomyelitis may be treated nonsurgically with long-term systemic therapy alone; however, this requires at least 6 weeks of antibiotic therapy.¹⁸⁴ Negative pressure wound therapy or hyperbaric oxygen therapy may be chosen when all other methods fail.

PREVENTION

Patients with sensory deficits from diabetic neuropathy are at risk for the development of ulcers. Those patients with associated arterial insufficiency are at even greater risk. Protective footwear, proven to be effective in reducing ulcer incidence,¹⁸⁵ is the first line of prevention and should be prescribed in any patient with significant neuropathy, previous amputation, previous ulcer, or anatomic foot deformity.¹⁸⁶ Those patients with healed ulcers have a nearly 60% risk of recurrence. For this reason, all at-risk patients need to be educated on daily foot care and inspection to identify at-risk areas to tailor interventions prior to ulcer formation. Appropriate long-term glucose control with reduction of hemoglobin A_{1C} is a necessity. Elevation of this serum marker has been correlated to cardiovascular disease, retinopathy, neuropathy, nephropathy, and a predictive factor for the formation of foot ulcers.¹⁸⁷

At-risk patients need annual foot examination that includes assessment for anatomic deformities, skin breaks, nail disorders, further loss of protective sensation, quantification of arterial supply, and proper footwear.¹⁸⁸ These evaluations should be done more frequently as the patient condition warrants. Thick callus or callus with adjacent subcutaneous hemorrhage suggests impending ulceration and requires removal to aid in reduction of the plantar surface pressure. Diagnosis of onychomycosis, fungal infection of the nails, carries additional morbidity to these patients and is present in about one third of patients with diabetes. These brittle nails provide a portal of entry for injection of harmful bacteria into the surrounding tissue, leading to a destructive infection. Treatment options include topical or systemic therapy and even nail ablation.¹⁸⁹

Chronic wounds are a distinct entity with multiple etiologies and contributing factors. They require a detailed evaluation of ulcer history, comorbidities, clinical examination, and diagnostic modalities to adequately formulate an effective treatment plan. Without this close attention, chronic wounds will consistently lead to significant morbidity and even mortality.

38 POSTOPERATIVE AND ADJUNCTIVE WOUND CARE

Michael Schurr, MD, FACS, and Lee Faucher, MD, FACS

Physiology of Wound Healing

A discussion of postoperative and adjunctive wound care hinges on two major concepts. The first is that wounds are a major source of complications in surgery and the second is that many wound-related complications can be avoided by a sound, evidence-based approach to wound care. It is beyond the scope of this chapter to discuss all surgical wounds in detail; however, the guiding surgical principles of wound care can be equally applied to a variety of procedures, such as inguinal herniorrhaphy or median sternotomy. Both are examples of subspecialty surgical incisions that have a significant body of literature related to the prevention and treatment of postoperative wound complications. Likewise, many other surgical incisions (mastectomy, cesarean section, rotational flaps, etc.) have unique data that guide the surgeon's clinical management. The data associated with each operative procedure need to be understood in detail to optimize patient outcomes.

An understanding of the physiology of wound healing is important in understanding the clinical approach to wound care. There are well-described, classic stages of wound repair. Wounds in humans typically heal by scar formation; the injured soft tissue is replaced by an area of fibroblast-derived collagen matrix that bridges the defect in the normal tissue. The body's initial response to wounding is to achieve hemostasis. This is the start of the inflammatory phase of wound healing. Vasoconstriction, platelet plugging, and activation of the coagulation cascade stop ongoing hemorrhage from the wound. Chemoattractants are released to recruit functional cell types that promote the healing process. Inflammatory cells infiltrate the wound; neutrophils appear within hours to remove damaged tissue and bacteria, and monocytes and macrophages appear within 48 to 72 hours. The proliferative phase begins with this shift away from a neutrophil-dominated wound to one that is controlled by macrophages and lasts for 7 to 10 days. A variety of additional cell types infiltrate the wound, including endothelial cells for angiogenesis, fibroblasts and macrophages to restore extracellular matrix and scaffold, and keratinocytes to restore barrier function and resurface the wound. The remodeling phase begins after resurfacing of the wound surface by keratinocytes. It typically begins 1 to 2 weeks after wounding and is a longer-term process that organizes collagen and strengthens the wound as the role of the other cell types diminish.

There are many excellent reviews on wound healing physiology that should be referred to for greater detail.¹ Our goal as surgeons is to ensure that the phases of wound care proceed in an orderly fashion and are not disrupted by inadequate blood flow, bacterial contamination, necrotic

tissue, immunosuppression, or other factors associated with postoperative wound complications.

This chapter discusses the preoperative and intraoperative factors that impact postoperative wound care. Wound closure techniques are reviewed using the laparotomy incision as the model for discussion of postoperative and adjunctive wound care as these techniques can be applied to a variety of surgical incisions. A large part of this chapter focuses on the management of wound-related complications, particularly wound infection, or surgical site infection (SSI). In 1999, the Centers for Disease Control and Prevention (CDC) published the "Guideline for the Prevention of Surgical Site Infection" and categorized SSIs as superficial incisional, deep incisional, or organ/space² [see Table 1]. Many of the clinical data on postoperative wound complications focus on SSIs as the primary end point or study outcome; thus, prevention of SSIs becomes the benchmark for efforts to clinically improve postoperative wound care.

Preoperative Considerations

It is important to understand the etiology of wounds. Chronic wounds are secondary to a disease state or failure of one of the phases of wound healing and are discussed elsewhere. Acute wounds can be broadly described as incisional or traumatic, and incisional wounds can be created in either elective or urgent/emergent situations. Traumatic wounds have a higher risk of postoperative complications as the environment is not sterile, no antibiotics are administered prior to the wounding event, and there is often significant delay before the repair because of patient transport, stabilization, and prioritization of treatment goals. In this setting, wound complications are common and often unavoidable. Likewise, higher postoperative complication rates can be expected for surgically created wounds in emergent or urgent situations than for those created during elective surgical procedures.

The elective operation, therefore, is the model for best practices in the preoperative preparation of a surgical patient to optimize postoperative wound healing and reduce the incidence of postoperative wound complications to the lowest level attainable. Fortunately, the incidence of wound complications can be reduced by appropriate care, but the argument that SSIs are completely preventable is erroneous and distorts the patient's expectation of what impact the surgeon has on complications after surgery. It is important for patients to know, preoperatively, their individualized risk assessment for postoperative wound complications. It is also important for patients to know that the surgeon takes advantage of all measures designed to reduce these complications.

Table 1 Criteria for Defining a Surgical Site Infection (SSI)

Superficial Incisional SSI

Infection occurs within 30 days after the operation and infection involves only skin or subcutaneous tissue of the incision and at least one of the following:

1. Purulent drainage, with or without laboratory confirmation, from the superficial incision
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
3. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat and superficial incision is deliberately opened by surgeon, unless incision is culture negative
4. Diagnosis of superficial incisional SSI by the surgeon or attending physician

Deep Incisional SSI

Infection occurs within 30 days after the operation if no implant is left in place or within 1 year if the implant is in place and the infection appears to be related to the operation and infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision and at least one of the following:

1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site
2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: fever ($> 38^{\circ}\text{C}$ [100.4°F]), localized pain, or tenderness, unless site is culture negative
3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of a deep incisional SSI by a surgeon or attending physician

Organ/Space SSI

Infection occurs within 30 days after the operation if no implant is left in place or within 1 year if the implant is in place and the infection appears to be related to the operation and infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation and at least one of the following:

1. Purulent drainage from a drain that is placed through a stab wound into the organ/space
2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of an organ/space SSI by a surgeon or attending physician

Adapted from Mangram AJ et al.²

PREOPERATIVE RISK REDUCTION

Smoking Cessation

Tobacco abuse can have a profound negative impact on a variety of wound- and non-wound-related postoperative patient outcomes. Fortunately, smoking cessation can improve many of these outcomes. The most significant smoking cessation benefit is a reduction in postoperative wound complications. In a randomized trial of 120 patients, smoking cessation 6 weeks prior to elective surgery reduced cardiovascular and other complications and reduced the wound complication rate from 31% in smokers to 5% in those who stopped smoking.³ We can also conclude that in nonelective situations, or in elective surgeries in which the patient is unable to stop smoking for 6 weeks, wound-related complications would be expected to occur in almost one third of patients.

Patients respond positively to physician intervention for high-risk behaviors such as tobacco abuse, and the ability to quantify and personalize the risk associated with the behavior makes the intervention more powerful. There are a variety of methods for smoking cessation, including stopping cold turkey, counseling, help-lines, and prescription medications combined with counseling. Preoperative patient education and the risk-benefit consenting process should include information that smoking cessation would result in a major risk reduction prior to elective operation. Ideally, elective operations should be delayed until 6 weeks after successful smoking cessation.

Glycemic Control

Patients with diabetes mellitus are, in general, at increased risk for complications during and after surgical procedures,

and those with an elevated preoperative hemoglobin A_{1c} level greater than 7% have an increased risk of postoperative infectious complications.⁴⁻⁶ Hemoglobin A_{1c} levels are representative of long-term glucose control as elevated glucose levels result in increased glycosylation of hemoglobin. It seems reasonable to maximize the medical therapy for the patient with diabetes who requires elective surgery to reduce postoperative wound complications. Adjustments may need to be made to diet, activity, oral hypoglycemic agents, and/or insulin. Consultation with the primary care physician or endocrinologist may facilitate this process. Patients with diabetes and elevated hemoglobin A_{1c} should understand their elevated risk of wound-related complications. Patients should be educated on the postoperative infection risk reduction that accompanies improved blood glucose control prior to elective surgery. Postoperative glycemic control may also have additional, non-wound-related, patient benefits for those critically ill in an intensive care unit.

Weight Loss in the Obese Patient

Obesity, defined by the CDC as a body mass index (BMI) greater than 30, is also associated with a higher incidence of wound complications. BMI should be considered when deciding whether to perform elective operations; that is, the risk of the operation, the risk of operative delay, and the benefit of substantial weight loss should be weighed against the realistic chance that the patient may or may not be able to lose weight. Obesity is associated with an increased risk of SSIs, dehiscence, and hernia after colorectal surgery.⁷ In addition to wound complications, obese patients undergoing rectal resections have longer operative times and an increased risk of conversion to an open procedure.⁷

Preoperative Nutrition

Adequate nutrition is essential to provide metabolic support for wound healing. BMI and prealbumin and albumin levels are helpful in identifying patients who are malnourished and may need nutritional support. An assessment of all three parameters gives a more complete assessment of nutritional risk. For example, the patient with low BMI but normal albumin and prealbumin is likely not malnourished. Elderly patients, patients with chronic illnesses such as cancer, and patients institutionalized in long-term care facilities are at the greatest risk for malnutrition and postoperative complications. Malnutrition is associated with an increased risk of SSIs and fascial dehiscence. Importantly, in those who are able to tolerate delays in operative intervention, 4 weeks of preoperative nutrition improves wound healing.⁸ Even 7 to 10 days may result in patient benefit if elective surgery cannot be delayed for 4 weeks. In addition, reassessment of the at-risk patient is useful as nutritional supplementation after surgical procedures is also beneficial. Postoperative nutritional supplementation reduces length of stay and wound-related complications in malnourished and undernourished patients.⁹

Coagulopathy

Preexisting coagulopathy should be diagnosed through careful medical and family history taking. Coagulopathies attributable to medical treatment with drugs such as warfarin should be reversed prior to surgery and bridged with shorter-acting anticoagulants if necessary. Even in those patients without coagulopathy, prophylactic preoperative heparin is often administered. Heparin administration to prevent venous thromboembolism may be indicated depending on an individualized risk assessment using nationally published guidelines; however, the risk of venous thromboembolism should be weighed against the increased risk of wound hematoma.¹⁰

Antiplatelet agents such as aspirin or clopidogrel may need to be stopped 2 weeks prior to surgery to allow for full platelet recovery if intraoperative and postoperative hemorrhage would result in major complications, such as in ocular or neurologic surgery. Unfortunately, the number of patients who require anticoagulants or antiplatelet agents is increasing. The risks associated with the discontinuation of therapeutic anticoagulant or antiplatelet agents must be balanced with the patient's operative risks. In addition, the risks associated with initiating prophylactic anticoagulants must be balanced with the patient's risk of venous thromboembolism. In some patients, the anticoagulant or antiplatelet agents are self-limited. For example, the patient treated with clopidogrel after arterial stent placement or warfarin after venous thrombosis may have therapy discontinued after a set time period, that is, 3 or 6 months. Elective operations in this patient population should be delayed until therapy has been discontinued unless operative delay would be associated with additional patient risk or complications.

OPERATIVE DAY RISK REDUCTION

Skin Preparation Techniques

Preoperative bathing or showering has been extensively studied and has no proven reduction in SSIs. No differences

among chlorhexidine gluconate, bar soap, or placebo were detected in these trials.¹¹

Preoperative hair removal has also been extensively studied. The hair removal concern relates to the superficial damage to the skin that can occur while shaving with a razor blade. Microscopic injuries to the epidermis are thought to be portals of entry for bacteria. In a recent review of 11 randomized, controlled trials of hair removal prior to surgery, the overall conclusion is that hair removal by shaving with a blade is associated with an increase in SSIs and should be avoided when possible.¹² Depilatory creams or clippers should be used instead and have no proven increase in SSIs. Additionally, routine shaving is likely unnecessary and could be avoided completely in a variety of incisions. In those who require preoperative hair removal, the timing of hair removal is irrelevant. Hair removal by clipping or depilatory up to 24 hours prior to incision is well tolerated and not associated with an increase in SSIs.¹² In other words, hair removal the day prior to incision with an electric clipper is a better option than shaving with a blade in the operative suite.

Preoperative Antibiotic Administration

The rationale for preoperative antibiotic administration is specific to the particular procedure and disease state. For example, the rationale for the use of oral and intravenous antibiotics prior to colectomy, or the particular antibiotic regimen chosen prior to median sternotomy, hysterectomy, laryngectomy, etc., is supported by specific clinical data related to those subspecialty areas. The antibiotic chosen is guided by the bacterial spectrum that the patient is exposed to during the operation and the individual center's antimicrobial sensitivity biogram. Preoperative antibiotics are often routinely administered, but in short, elective, clean operations, such as inguinal herniorrhaphy, there are conflicting data, with prospective trials both advocating for and against preoperative antibiotics.^{13–15} If an antibiotic is to be administered, the tissue levels should be maximal at the time of incision and during the operation. Antibiotics administered too long prior to the operation lose effectiveness, as do antibiotics administered after incision. The timing of antibiotic administration clearly impacts wound infection rates; antibiotic administration within 2 hours prior to incision should result in a postoperative infection rate of less than 1% for clean and clean-contaminated, elective operations.¹⁶ Extended-length operations may require redosing of the antibiotic depending on the duration of the procedure and the half-life of the drug administered.

Preparation for Colonic Surgery

Randomized, controlled trials have shown that in elective colonic surgery, combined oral and systemic antibiotics are superior to systemic antibiotics alone in preventing SSIs.¹⁷ The oral antibiotic protocol is institutional dependent but often includes the nonabsorbable neomycin with or without erythromycin. The preoperative preparation prior to colectomy may or may not also include mechanical bowel preparation to remove fecal material from the colon prior to surgery. Mechanical bowel preparations use laxative solutions that cause diarrhea but may cause abdominal cramping, dehydration, and electrolyte imbalances. Mechanical bowel preparations are essential prior to colonoscopy to visualize the

mucosa, but as an adjunct to colectomy, there is no significant reduction in the rate of postoperative SSIs, anastomotic leaks, or intra-abdominal abscesses in patients who receive mechanical bowel preparation compared with no bowel preparation.¹⁸

Intraoperative Considerations

SURGICAL WOUND CLASSIFICATION

Specific intraoperative findings such as bacterial contamination will impact the risk of postoperative wound complications. The impact of the degree of intraoperative bacterial contamination on postoperative wound complications is well established. The Surgical Wound Classification has been widely adopted for assessment of patient risk [see Table 2].² In some, bacterial contamination occurs as part of the disease process, for example, in those with perforated sigmoid diverticulitis. In others, careful surgical technique is an essential, modifiable factor to prevent intraoperative contamination and subsequent postoperative wound complications. For example, laparotomy for lysis of adhesions in a patient with a small bowel obstruction is a class I/clean case unless an enterotomy is made, at which time, it becomes a class II/clean-contaminated case with an inherent higher risk of wound complications and SSI. Similarly, spillage from a colonic injury with fecal contamination would result in a class III/contaminated operation. Careful, meticulous surgical technique is essential to minimize patient risk of SSI.

Laparotomies are often class II/clean-contaminated procedures as a result of planned entry into the biliary, gastrointestinal, or urinary tract. Many of these procedures have a risk of wound complications only slightly higher than the risk in patients undergoing class I/clean operations. The colon, however, has very high concentrations of bacteria, and colonic resection is associated with bacterial contamination, SSIs, and wound complications. Colon resection is an example of an operative procedure in which best practices may be able to reduce postoperative wound complications. In a prospective study of 2,809 consecutive patients undergoing elective colorectal resection, the overall incidence of SSI was 4.7%.¹⁹ In this study, the factors that predicted SSI were American Society of Anesthesiologists (ASA) score, surgical wound class, blood transfusion, need for ostomy, type of operation, use of drains, male gender, and surgeon's experience.

The postoperative SSI rate after colectomy varies widely, ranging from 5 to 10% in randomized, prospective trials of elective colorectal resection.^{18,19} These rates of SSIs are clearly higher than the incidence of SSIs after class I/clean operations. A thorough preoperative risk assessment and risk reduction, if necessary, are important to maximize patient outcomes. SSIs and postoperative wound complications are complex and multifactorial and not completely preventable, and a thorough discussion of the 5 to 10% risk of SSI after colectomy should be held with the patient during the preoperative evaluation process.

HYPEROXIA AND WARMING

Perioperative Hyperoxia

Other clinical maneuvers, for example, perioperative hyperoxia and perioperative patient warming, have been studied in an effort to reduce the incidence of postoperative wound complications. Unfortunately, the initial promising results of perioperative hyperoxia have not been reproducible or have been outright refuted in follow-up trials, causing confusion. Perioperative hyperoxia, or 80% inspired supplemental oxygen, was shown to reduce SSIs by 10% in a randomized, controlled clinical trial of patients undergoing colorectal operation.²⁰ Another randomized, controlled trial of laparotomy patients had the opposite conclusion, with a 13% increase in SSIs in those who received supplemental perioperative oxygen.²¹

It should be noted that these trials showed a 24% incidence of SSI in patients prospectively evaluated following colorectal operations and an 11% incidence of SSI in patients prospectively evaluated following laparotomy. A more recent review of five randomized, controlled trials concluded that hyperoxia resulted in SSI absolute risk reduction of 3.0%, with the benefit being greater in colorectal operations.²² It seems reasonable to assess the overall institutional risk of SSI and wound complication after colectomy and use perioperative hyperoxia if the institutional risk is higher than the 5 to 10% acceptable risk described in the literature.

Perioperative Warming

Patient warming in the perioperative period reduces SSIs after colorectal and clean surgical procedures.^{23,24} A review of 19 randomized, controlled warming trials showed that perioperative warming of surgical patients is effective for reducing

Table 2 Surgical Wound Classification

Class I/Clean: An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow nonpenetrating (blunt) trauma should be included in this category if they meet the criteria.
Class II/Clean-Contaminated: An operative wound in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category provided that no evidence of infection or a major break in technique is encountered.
Class III/Contaminated: Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract and incisions in which acute, nonpurulent inflammation is encountered are included in this category.
Class IV/Dirty-Infected: Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation.

Adapted from Mangram AJ et al.²

postoperative wound pain, wound infection, and shivering.²⁵ Patients often lose body heat during surgical procedures, and this effect is more pronounced with an open body cavity, such as with laparotomy. Laparotomies and thoracotomies often last for more than 1 or 2 hours, and the heat loss may be progressive if not carefully monitored and treated. Generalized warming options exist, including increasing the temperature of the room, the intravenous fluids, and the inspired gases. Forced air warming is readily available and easy to use during the operation and afterward during the recovery period. Early efforts at preventing heat loss are often easier than attempts to rewarm the patient. In particular, it is important to keep the patient covered and warm during anesthesia induction and patient preparation prior to sterile draping.

FASCIA CLOSURE TECHNIQUES

The laparotomy incision and closure are useful to examine further as the variety of patient disease states, procedures, incisions, and contamination classifications result in a wide variety of postoperative wounds that often require creative adjunctive techniques for definitive management. Given the wide variations among different patient populations and different surgical procedures, definitive prospective clinical data are difficult to generate.

One technique that has been studied prospectively is the suturing technique for closure of abdominal wall fascia. It is now fairly well accepted that a continuous suturing technique is as effective as an interrupted suturing technique, with the added advantage of being a faster fascial closure.²⁶ A prospective evaluation of the length of suture used highlighted the importance of the technical aspects of fascial closure. Multivariate analysis identified the ratio of suture length to wound length, age, and major wound infection as independent risk factors for the development of hernias.²⁷ A closure technique that uses a length of suture four times longer than the length of the fascial defect is important in reducing hernia formation. Placement of larger fascial bites closer together results in increased suture length use compared with smaller bites spaced further apart.

In summary, mass closure incorporating all layers of the abdominal wall (except skin) as one structure, in a simple running technique, using #1 or #2 absorbable monofilament suture material with a suture length to wound length ratio of 4 to 1, is recommended.²⁸ Absorbable monofilament sutures have longer wound duration and provide additional fascial security compared with more rapidly absorbed suture. Permanent suture material is associated with a risk, although small, of delayed stitch abscess formation that ultimately requires suture removal for cure. This is particularly true of braided permanent sutures, which have numerous interstices that can harbor bacteria.²⁹ Ultimately, the choice of a suture material should be individualized to the patient and clinical situation.

Postoperative Considerations

EARLY FASCIA COMPLICATIONS

Complications of fascia closure can be divided into those that occur in the immediate postoperative setting versus the

delayed complications of incisional hernia. Early fascia closure complications are often severe and life-threatening. These include SSI, dehiscence, evisceration, and necrotizing fasciitis. Dehiscence and evisceration are associated with significant morbidity and mortality [see *Figure 1*]. Fortunately, dehiscence with or without evisceration is unusual but common enough that every surgeon who performs abdominal surgery will have these complications. Clinically recognized acute laparotomy wound failure and dehiscence rates are 1 to 2%.^{26,30} Unrecognized dehiscence likely results in late hernia formation. Many nonpreventable comorbidities, such as ASA class, trauma, peritonitis, age, gender, chronic obstructive pulmonary disease, ascites, jaundice, anemia, emergency surgery, postoperative coughing, and class III–IV/contaminated or dirty-infected wounds, increase the risk of acute wound failure.^{31,32} The management of early fascia complications is summarized in Table 3.

Dehiscence and Evisceration

Dehiscence is often heralded by serosanguinous drainage from the wound between 5 and 10 days after surgery. In some cases, this may even occur after the patient is discharged. Dehiscence, and the rarer evisceration, is associated with significant morbidity and mortality; therefore, postoperative wound drainage cannot be ignored. It is a marker that the fascia has failed either from a primary failure of fascial closure or as a manifestation of an intra-abdominal complication such as anastomotic leak or intra-abdominal abscess.

One should perform fascial exploration by reopening the skin incision. Patients with dehiscence require urgent or emergent reexploration. It is important to realize that the abdominal wall can fail from pathology related directly to the abdominal wall fascia itself (deep incisional SSI) [see *Table 1*] or as a manifestation of an intra-abdominal catastrophe such as anastomotic leak or intra-abdominal abscess (organ/space SSI) [see *Table 1*]. Both should be treated therapeutically with antibiotics, that is, preoperative broad-spectrum antibiotics

Figure 1 Postoperative dehiscence and evisceration through a laparoscopic port site after a vigorous coughing episode. Note the ischemic section of bowel that requires resection.

Table 3 Management of Early Fascia Complications

Diagnosis	Differential Diagnosis	Treatment	Fascia Closure Options	Skin Closure Options
Dehiscence or evisceration	Deep incisional SSI Organ/space SSI Necrotizing fasciitis	Bacterial culture Antibiotics Drainage of infection	Suture repair	Secondary intention
Necrotizing fasciitis	Superficial incisional SSI Deep incisional SSI Organ/space SSI	Bacterial culture Antibiotics Radical débridement	Suture repair if possible Absorbable mesh Biologic mesh Negative pressure wound therapy	Skin grafts Secondary intention
Abdominal compartment syndrome		Resuscitation Bogota bag Negative pressure wound therapy	Delayed suture repair after edema resolves Planned ventral hernia Biologic mesh	Secondary intention Primary closure only if planned ventral hernia or biologic mesh
Need for relook laparotomy		Temporary skin closure Bogota bag	Suture repair	Secondary intention
Fascia loss and skin cannot be closed			Absorbable mesh Biologic mesh Negative pressure wound therapy	Skin grafts Secondary intention
Fascia loss and skin can be closed			Planned ventral hernia Biologic mesh	Primary closure

and postoperative culture and sensitivity-directed antibiotics. Efforts should be made to fully evaluate the cause of the acute abdominal wall failure with preoperative imaging if possible and with a thorough abdominal exploration during the operation. Cultures should be taken at the fascial level and of any deeper fluid collections to guide antibiotic therapy.

Reclosure should incorporate all of the layers of the abdominal wall using running #1 or #2 absorbable monofilament suture material with a suture length to wound length ratio of 4 to 1.²⁸ However, an intraoperative decision is required as to whether the abdominal wall can be simply reclosed. There may be a need for reexploration at 24 or 48 hours that will delay definitive closure and require temporary closure techniques. In those patients who can be definitively reclosed at the time of laparotomy, all best practices should be followed (patient warming, timing of antibiotic administration, suture technique, etc.) and the skin should be left open to heal by secondary intention. The duration of antibiotic therapy should be guided by the patient's clinical course (fever, white blood cell count, evidence of granulation tissue ingrowth into the wound) but typically continues for 7 to 10 days.

Historically, large retention sutures were placed through the entire substance of the abdominal wall, including fascia and skin lateral to the linea alba at the midrectus-abdominus location. These sutures were placed as mechanical efforts to stabilize the abdominal wall in patients at high risk for postoperative acute laparotomy wound failure or at the time of reexploration in those patients with postoperative dehiscence. Retention sutures were thought to prevent bowel evisceration but have proven to be largely unsuccessful and associated with complications.^{33,34}

Necrotizing Fasciitis

Necrotizing fasciitis is a rare, often idiopathic, diagnosis that develops de novo, after trauma, or in patients with open

wounds. The risk factors of immunosuppression, obesity, or diabetes mellitus are found in 80% of patients.³⁵

Fortunately, necrotizing fasciitis is a rare complication after laparotomy, but the diagnosis can be difficult and the associated mortality is very high, especially with operative delay. Patients typically present with extreme pain, swelling, and fever.³⁶ The early examination may be fairly unremarkable, with pain, warmth, and erythema as the only changes noted to the skin. Often the initial diagnosis is superficial incisional SSI, and patients are treated with antibiotics; however, rapidly spreading erythema surrounding the wound requires emergent wound and fascial exploration. Other clues to the diagnosis of necrotizing fasciitis are bullae formation, skin necrosis, and crepitance. Roentgenograms may show subcutaneous emphysema.

In a review of 89 patients treated at a single institution, only four (4.5%) patients developed necrotizing fasciitis as a postoperative complication, so the vast majority of cases have no obvious source for the infection.³⁶ In these four cases, three occurred after class III/contaminated procedures and one occurred after a class II/clean-contaminated operation.

Once the diagnosis of necrotizing fasciitis is entertained, resuscitation, antibiotic administration, and emergent radical débridement of all involved tissues are essential to ensure patient survival.³⁷ Débridement must be performed without regard to later reconstruction as ensuring survival is the immediate goal. All tissue planes that are involved with the infectious process must be opened even if the overlying skin looks normal and uninvolved. Often the only clue to the spread of infection is "dishwater"-appearing fluid draining from between the tissues. Necrotizing fasciitis commonly dissects in the plane between the fascia and subcutaneous fat; this plane needs to be defined and opened, and all necrotic tissue débrided. Wide opening of the involved area facilitates postoperative dressing changes. Late reconstruction by secondary closure, flaps, or skin grafts is performed electively,

after granulation tissue forms, and in an otherwise stable patient. If the large open wound is beyond local capabilities, the patient can be transferred to specialized burn centers that have experience with patients with large open wounds. It is important to consider interhospital transfer only after radical débridement as any delay in controlling this rapidly spreading infection will worsen patient outcomes.

The Open Abdomen

Temporary closure for early reexploration There are patients in whom fascial closure is desired, but the fascia is unable to be closed primarily. This may be because the fascia has been extensively débrided as a result of necrotizing fasciitis or fascial necrosis. Massive edema of the bowel and intra-abdominal contents following trauma or abdominal catastrophe also prevents fascial closure to avoid abdominal compartment syndrome. Finally, there are patients with primary abdominal wall failure who require relook laparotomy at 24 or 48 hours. For example, in cases of damage control laparotomy after abdominal trauma or patients with small bowel thromboembolism, reexploration at 24 or 48 hours is common.

A variety of temporary abdominal closure techniques have been developed to aid in the management of this diverse group of patients. The fascia can be left open with skin-only closure using interrupted sutures or interrupted towel clips holding the skin edges together. Temporary skin closure offers the advantages of not further damaging the fascia with sutures, which require subsequent removal, as well as speed and ease of reopening at the time of reexploration. An alternative to the towel clip technique is to sew a large sterile sheet of plastic (Bogota bag) to the fascia or skin [see Figure 2a]. Typically, a 3 L irrigation bag is used as the size fits the midline laparotomy incision. The clear plastic allows for visualization of the abdominal contents postoperatively, which may be advantageous in the patient with bowel ischemia. This technique is also convenient in those patients who need rapid closure of the abdomen with planned reexploration but have significant bowel edema that precludes temporary skin closure with towel clips. Sewing the temporary plastic bag to the skin also offers the same advantage of avoiding injury from fascial suture placement until the time of definitive abdominal wall closure, that is, after resolution of bowel wall edema.

Planned ventral hernia In those in whom fascial closure is desired but not attainable because of fascial loss or intra-abdominal edema preventing primary suture repair, the morbidity and mortality are significant. Patients can be divided into two broad categories, one in which skin can be closed and one in which skin closure is not feasible. In patients in whom the skin can be primarily closed, one can simply close the skin over the fascial defect, essentially creating a large incisional hernia that will require delayed repair.

Another option is to use an absorbable mesh (e.g., polyglactin 910) to bridge the fascial closure and then close the skin over the top of the absorbable mesh. Obviously, in the setting of the open abdomen, permanent, prosthetic mesh (e.g., polypropylene) repair of the abdominal wall has an overwhelming rate of mesh infection and is contraindicated. Absorbable mesh gives some stability to the abdominal wall in the early postoperative period but will eventually form an

Figure 2 (a) Temporary closure of the abdominal wall after extensive blunt force trauma with a 3 L saline bag (Bogota bag). Note the extensive fascia loss and the fact that the skin cannot be closed. (b) Reconstruction of the abdominal wall with biologic mesh. After several weeks of granulation tissue ingrowth, skin grafts were placed for final wound closure.

incisional hernia that requires late repair. In addition, there are a wide variety of biologic meshes made from human dermis, pig dermis, or pig submucosa that are used in cases with bacterial contamination that preclude the use of permanent, prosthetic mesh. Advocates for the use of biologic mesh in this setting claim that the need for late ventral hernia repair can be reduced as the biologic material can result in long-term stability of the abdominal wall. Biologic mesh has been adopted by some for elective herniorrhaphy, but prospective clinical data comparing outcomes in complicated primary abdominal wall failure and the open abdomen are lacking.

Alternative closure techniques for the open abdomen In the patient in whom fascial closure is desired but not attainable, and in whom the skin cannot be closed, two approaches exist to eventually attain closure of the abdominal wall. These patients have significant morbidity and mortality and are at risk for the development of an enterocutaneous fistula.

Typically, either absorbable mesh or negative pressure wound therapy is used to stabilize the abdominal wall and oppose contractile forces from the rectus muscle components and lateral oblique muscles. Negative pressure wound therapy reduces bowel edema and encourages granulation tissue ingrowth so that split-thickness skin grafts can be placed over the granulating bed and close the wound. Alternatively, absorbable mesh (or biologic mesh) is used to bridge the fascial defect, followed by dressing changes until granulation tissue forms under the mesh. The mesh is removed, and split-thickness skin grafts are placed to close the wound [see Figure 2b].³⁸

In a single-institution, prospective, randomized trial comparing morbidity and mortality differences between the absorbable mesh and negative pressure wound therapy, the fistula rate was 21% in the negative pressure wound therapy group and 5% in the absorbable mesh group. There was no statistical significance between these groups, possibly because of a lack of power in the study, but this study demonstrates the morbidity associated with an open abdomen. The fistulas were felt to be related to feeding tubes, suture line areas, or bowel perforation remote to the anastomotic site.³⁹ All of these patients will require late abdominal wall reconstruction using complicated techniques for skin graft removal, fascial reconstruction, and restoration of skin continuity.

LATE FASCIA COMPLICATIONS (INCISIONAL HERNIA)

Risk factors for incisional hernia after laparotomy are similar to the risk factors for SSI. Redo laparotomy was the strongest factor associated with hernia, and other risk factors included smoking, postoperative wound complications, age, and male gender.⁴⁰ The incidence of incisional hernia after laparotomy is difficult to determine exactly but has been reported to be as high as 15 to 25% in different studies.⁴¹ Incisional herniorrhaphy techniques have evolved extensively in recent years, and a thorough understanding of the risks and benefits of primary repair, mesh closure by bridging or underlay technique, Rives-Stoppa repair, component separation, and laparoscopic versus open repair is essential to individualize the approach to the patient.

SKIN CLOSURE TECHNIQUES

Primary, Secondary, and Tertiary Closure

Intraoperative findings dictate how skin closure is managed after fascia closure. Class I/clean cases are typically closed by primary closure; that is, the skin is closed by suture or staple technique, and the technique of continuous versus running suture closure has not been shown to impact overall outcome. However, interrupted closure is advisable in those patients in whom primary closure is used in the setting of a class II/clean-contaminated operation so that a portion of the wound can be opened in patients who develop SSI. The interrupted closure allows an area of concern in a wound to be reopened without disrupting the entire wound. Staples are often used as a rapid, interrupted closure technique with good cosmetic outcome compared with interrupted sutures.

Class III–IV/contaminated or dirty-infected wounds are typically closed by secondary or tertiary closure. Secondary closure allows for the wound to heal completely by wound contracture, granulation tissue ingrowth, and keratinocyte

resurfacing from the margins of the wound. This process can be prolonged and associated with pain and quality of life issues [see Figure 3, a and b].

The last technique is tertiary, or delayed primary closure. The skin is not closed at the time of the original operation but at some delayed time after local wound management techniques are employed to reduce bacterial counts. Typically, sutures are placed at the time of the original operation but not tied or secured, and gauze dressing changes are performed in the open wound. When the wound bed changes from a draining, inert wound to a dry wound with healthy-appearing margins, the sutures are tied. This typically occurs 3 to 5 days later.

In a prospective evaluation of patients with class III–IV/contaminated or dirty-infected surgical wounds, tertiary closure was associated with a statistically significant reduction in SSI compared with primary closure.⁴² This reduction in SSIs using closure by secondary intention or delayed primary closure (tertiary closure) must not be minimized as SSIs are

Figure 3 (a) Large traumatic gluteal wound after crush injury. Extensive intraoperative débridement of all necrotic and damaged tissue prevented postoperative infectious complications. (b) Dramatic healing by secondary intention. At this time, skin grafts were placed for final wound closure.

a major risk factor for dehiscence, evisceration, and necrotizing fasciitis. In a randomized, controlled trial of 48 patients with colon injuries in which the skin wound was primarily closed or left open, wound infection developed in 65% of those with closed skin incision and 36% of those whose wounds were left open to close by secondary intention. Importantly, dehiscence developed in 31% of patients with primarily closed skin incisions and in only 14% of those left to heal by secondary intention.⁴³ Prevention of SSIs in patients with class III–IV/contaminated or dirty-infected wounds avoids the morbidity and mortality associated with complicated fascial and abdominal wall reconstruction in patients with primary abdominal wall failure in the postoperative setting.

Open Wounds

A variety of techniques are available for the management of postoperative wound healing by secondary closure, reopened wounds after failed primary closure, or wounds planned for tertiary closure. Unfortunately, there are few clinical data to support the management of these complicated patients.

In a recent review of dressings for patients with wounds healing by secondary intention, 13 randomized, controlled trials provided little evidence for any specific technique or dressing that would improve outcomes.⁴⁴ The gauze dressing, whether placed dry in an actively draining wound or saline moistened in a dry wound, has great efficacy in preparing the wound for closure by secondary or tertiary intention or by skin grafting. Gauze dressings may be associated with more pain than other dressings, but the cost and convenience are hard to ignore.

Specialty dressings are commonly altered to control wound fluid and to promote wound healing; however, their effect is probably more significant in patients with a chronic wound compared with those with acute postoperative wound complications. One of the advantages of specialty dressings may be in a reduction in the evoked pain associated with the dressing change or a reduction in perceived and anticipated pain associated with a less frequent dressing interval. The cost of the dressing must be weighed with the potential patient benefit as specialty dressings have not been shown to improve wound healing over saline gauze dressings.

Hematoma or Seroma

Acute postoperative wound fluid collections include hematomas, seromas, or lymphatic fluid. Hematomas and seromas can impair wound healing by mechanically disrupting the wound, causing pressure-related ischemia of the overlying skin, or by becoming secondarily infected, resulting in an SSI. Wound hematomas are common in those patients with prophylactic or therapeutic anticoagulation or antiplatelet therapy.⁴⁵ Fortunately, most wound hematomas associated with prophylactic anticoagulation are minor and do not require further therapy.

The risk of hematoma must be balanced with the risk of deep veins thrombosis and pulmonary embolism. Wound seromas are common in operations that result in large undermined skin and subcutaneous flaps and are also common in procedures that implant foreign material. The open incisional hernia repair that results in large skin/subcutaneous flaps and uses prosthetic mesh for the fascial repair is particularly prone

to seroma formation. Prevention is important; coagulation should be normalized preoperatively and restarted after 24 hours if possible. Meticulous attention to intraoperative hemostasis by suture ligation of subcutaneous vessels and electrocautery of other bleeding sites should prevent hematoma formation in those with normal coagulation parameters.

Patients with abnormal coagulation or ongoing antiplatelet therapy need careful postoperative monitoring with return to the operating room for hematoma evacuation if a substantial collection develops. Seromas are predictable in patients with foreign material or large dissection fields and flaps; therefore, closed-suction drains should be placed through separate incisions into the potential space to encourage coaptation of the edges. Large postoperative seromas or hematomas that develop despite meticulous surgical technique and prophylactic drain placement (or after drain removal) should be therapeutically drained or evacuated to prevent infection or wound ischemia. Wound fluid collections may reach high enough pressure that capillary perfusion pressure is exceeded. The resulting wound ischemia can lead to necrosis or SSI. The wound hematoma is a potential nidus for bacterial growth. Evacuation of the fluid or hematoma should prevent these complications. The initial decision that must be made is whether or not the fluid is putting the patient at risk for a wound-related complication. The therapeutic options are observation and reevaluation or drainage. Drainage can either be performed percutaneously or by reopening the incision and placing closed-suction drains. Aspiration is often attempted as first-line therapy and may be repeated as necessary or converted to open drainage if it proves ineffective.

Traumatic Wounds

Traumatic wounds are a setup for complications and deserve separate discussion. The traumatic wound is created without the advantage of antimicrobial skin preparation or prewounding antibiotic administration, and there is no opportunity for prewounding reduction of risk factors such as tobacco abuse. There is significant delay to definitive treatment and often additional soft tissue or bony damage in close proximity to the wound itself. Wounds should be evaluated for the presence of adjacent soft tissue injury or hematoma that requires exploration, débridement, or drainage. Foreign bodies are also common in these wounds and are a nidus for infection if not removed.

Management of the traumatic wound follows many of the same principles described above. On arrival at medical care, it is important to rapidly assess for ongoing hemorrhage that could require early formal wound exploration with ligation or repair of major or minor vessels. Wounds that will require further delay for patient stabilization and prioritization of injuries should be cleansed with an appropriate skin preparatory solution and covered with sterile gauze until definitive repair. Antibiotic administration is typically governed by other injuries; however, depending on the wound size, location, and degree of contamination, it may be reasonable to administer an empirical 5- or 7-day course of antibiotics. Less concerning wounds should be treated with antibiotics prior to definitive operative repair and in the immediate postoperative period.

Operative management of the traumatic wound must focus first on skin cleansing and the removal of all foreign material from the wound. Small wounds with large undermined edges should be opened widely to accomplish this goal. All necrotic tissue must also be removed, regardless of the resulting size of the final defect [see Figure 3a]. Wound irrigation with saline is commonly performed to thoroughly wash the wound of all remaining foreign material, clotted blood, or devitalized cellular debris. Wound irrigation typically is performed with a low-pressure, passive drainage system; however, high-pressure pulsatile lavage systems are available. The high-pressure systems may cause additional soft tissue damage and should be used with caution.

Reconstruction options are as varied as the types and causes of wounds. Primary repair of simple wounds suffices when wounds are clean and do not require substantial débridement of tissue such that no undue tension exists on the wound closure. Other options also include closure by secondary or tertiary intention. The large, complex wound that involves skin and deeper soft tissue structures may require temporary allograft or negative pressure wound therapy as a temporizing measure until flaps or skin grafts can be placed.

ADJUNCTS TO POSTOPERATIVE WOUND MANAGEMENT

Treatment of Superficial Incisional SSI

All SSIs are expensive because of the costs associated with the antibiotics administered and the increased length of stay in the hospital. Prevention measures are effective in reducing the incidence of SSIs, but SSIs are not completely preventable and are commonly diagnosed and treated. Deep incisional and organ/space SSI after laparotomy may result in dehiscence, evisceration, or necrotizing fasciitis as described above and are typically managed by surgical exploration, percutaneous drainage, or intravenous antibiotics. Other subspecialty incisions have a body of literature that guides treatment for SSIs, for example, treatment of deep incisional SSI following median sternotomy or total knee arthroplasty.

Superficial incisional SSIs are commonly encountered in surgical practice and should be considered in postoperative patients noted to have increasing warmth, pain, erythema, or drainage at the surgical site. The management depends greatly on the type of wound and the circumstance in which it was created. It is essential to rule out deep incisional or organ/space SSIs masquerading as superficial incisional SSIs. It is also important to establish the cause of the SSI. For example, in the posttraumatic wound SSI, one should consider the possibility of a retained foreign body that led to the infectious process. Alternatively, the SSI may simply be a manifestation of the risks involved with colectomy in a patient with multiple risk factors and a high ASA score.

Antibiotics are commonly used in SSIs and are mandatory in the patient with systemic symptoms, such as fever, or locally advanced symptoms, such as surrounding cellulitis. Likewise, cultures should be obtained in all but the simplest SSI. If the wound has an area of drainage, then opening of the wound is required to allow for complete drainage of the infectious process and facilitate dressing changes [see Figure 4a]. Any necrotic tissue requires surgical débridement. Dry gauze is used in draining wounds and should be changed frequently until the drainage subsides [see Figure 4b].

Figure 4 (a) Surgical site infection after laparotomy and bowel resection (class II/clean-contaminated). The skin was closed primarily with staples and reopened to heal by secondary intention. Note the small amount of necrotic material at the superior aspect of the wound and the resolution of the surrounding cellulitis after reopening the skin incision. (b) Gauze dressings are inexpensive, effective, and well tolerated for a wound this size.

Most superficial incisional SSIs will be left open to heal by secondary intention. A smaller subset of patients will have late presentation of SSI or failure of closure by secondary intention with the formation of a chronic wound sinus. The differential diagnosis should consider the presence of a foreign body, for example, a permanent suture knot with chronic infection, chronic infection of an implant, or the possibility of an enterocutaneous fistula.

Topical Silver

One of the significant ongoing debates in wound management focuses on the role of bacteria in impairment of wound healing. Class I–II/clean or clean-contaminated procedures can have primary closure of the skin with a very low and acceptable rate of SSI. Those with class III–IV/contaminated or dirty-infected operations are commonly managed with

closure by secondary intention or delayed primary closure. All would agree that postoperative wounds with surrounding cellulitis (edema, erythema, warmth, pain) require débridement of nonviable tissue, drainage of fluid collections, and systemic antibiotic therapy. Despite efficacy in those with thermal burns, it is unclear if additional topical antimicrobial agents (bacitracin, mupirocin, silver) improve healing of surgical wounds.

Many wound dressings are now impregnated with large quantities of silver, which can impair wound healing. It is recommended that silver-based products be avoided in situations where there are rapidly proliferating keratinocytes.⁴⁶ Preliminary in vitro and animal data on next-generation silver dressings containing lower silver concentrations show proliferation of cells involved in wound healing while reducing bacterial counts.⁴⁷ Unfortunately, there are no clinical trials demonstrating efficacy toward healing of the complicated, postoperative wound. Silver should probably be reserved for wounds with obvious bacterial contamination, and treatment should be stopped when the wound changes from one with purulent drainage to a dry wound with signs of ongoing healing.

Negative Pressure Wound Therapy

Negative pressure wound therapy deserves some additional discussion as it has gained tremendous popularity recently as a wound management technique. Negative pressure wound therapy has animal and preclinical data support, but prospective clinical human trials are lacking. The negative pressure applied to the wound through a suction apparatus connected to a sponge [see Figure 5] has been shown in animal studies to reduce bacterial counts and promote granulation ingrowth.⁴⁸ Negative pressure therapy has been applied to various wounds, including those with underlying exposed or infected bone, chronic wounds, temporary abdominal closure, and securing skin grafts with some success. For example, negative pressure wound therapy has been shown to be a safe and reliable option in poststernotomy mediastinitis compared with conventional treatment.⁴⁹ However, the role of negative pressure wound therapy in acute cutaneous wounds has fewer supporting data. Negative pressure wound

therapy offers some convenience to patients as dressings are typically changed every other day or every third day compared with the twice-daily schedule associated with gauze dressings. The reduction in the frequency of dressing changes must be weighed against the extra costs associated with negative pressure wound therapy and the limitations of patient mobility and freedom attributable to the required electrical or battery-powered apparatus.

Although preclinical and animal data suggest benefit, prospective clinical trials evaluating negative pressure wound therapy use in cutaneous wounds are required to define the cost/benefit of this technique. One contraindication to negative pressure wound therapy is infected wounds. Silver-based sponges are now available for this indication; however, clinical data to support the use of negative pressure wound therapy in the setting of infection are still pending.

Temporary Allograft Coverage

In the specialized burn patient population, temporary allografts are commonly used. Meshed cadaver skin promotes vascularization and reduces bacterial bioburden in cases where immediate autografting is not an option.⁵⁰ Cultured allogeneic keratinocyte grafts are another alternative and have been shown to speed healing of partial-thickness burns and improve cosmetic outcome.⁵¹ These techniques have also been applied to chronic wounds and complicated postoperative wounds, for example, the patient with large traumatic wounds or those patients requiring radical débridement of the abdominal wall, perineum, or extremity following necrotizing soft tissue infection.⁵² A temporary allograft can help control the pain associated with large open wounds, allows for physical therapy to resume, and can be a bridging, or temporizing, wound therapy until definitive closure is undertaken [see Figure 6].

Conclusions

Wounds are a major source of complications in surgery, and many wound-related complications can be avoided by a sound, evidence-based approach to wound care. A thorough evaluation for preoperative risk reduction with smoking

Figure 5 Negative pressure wound therapy after extensive débridement of necrotizing soft tissue infection. After granulation tissue ingrowth, skin grafts were placed.

cessation, glycemic control, weight loss in the obese patient, and nutritional supplementation in the malnourished patient all reduce postoperative wound complications. A sound strategy for the management of coagulopathy is essential to balance risk versus benefit. Proper skin preparation and dosing of antibiotics reduce SSIs, as do combined oral and systemic antibiotics prior to colectomy. Intraoperative hyperoxia and patient warming are effective for reducing postoperative wound complications.

Abdominal wall mass closure incorporates all of the layers of the abdominal wall (except skin) as one structure, in a simple running technique, using #1 or #2 absorbable monofilament suture material with a suture length to wound length ratio of 4 to 1. Unfortunately, dehiscence occurs in 1% of patients after colectomy and is heralded by serosanguinous drainage from the wound between 5 and 10 days after surgery. These patients may have primary failure of the abdominal wall attributable to a technical problem or

organ/space SSI and intra-abdominal pathology that requires further treatment.

Some patients, unfortunately, will develop an open abdomen and require advanced and prolonged treatment. Those in whom skin closure is not feasible are typically managed by the absorbable mesh technique or negative pressure wound therapy. Both options are associated with fistulas. Prevention is clearly a better option. In those with class III–IV/contaminated or dirty-infected surgical wounds, secondary closure is associated with a statistically significant reduction in SSI and dehiscence compared with primary closure. Gauze dressings are cheap and effective but associated with frequent and often painful dressing changes. A wide variety of adjuncts (specialized dressings, silver dressings, negative pressure wound therapy, temporary allograft coverage) may benefit patients, but clear clinical data are currently lacking.

1 CARDIAC SYSTEM

Raja R. Gopaldas, MD, and Scott A. LeMaire, MD

The circulatory system, which consists of the heart, arterial system, venous system, and lymphatics, has long remained a source of fascination for anatomists and physiologists alike. The unique anatomic and physiologic characteristics of the heart not only make it somewhat challenging for basic scientists to understand but also impose significant technical challenges for surgeons who operate on the heart. The heart not only pumps blood to the entire body: it is also responsible for supplying its own nutrition via the coronary arteries, damage to which could initiate a detrimental cycle. Several unique compensatory anatomic and physiologic mechanisms ensure the long-term durability and functional integrity of the heart. Over the average 70-year human life span, the heart contracts about 2.75 billion times without interruption—which still far exceeds the durability of some of the best mechanical devices made by humans.

History

Claudius Galenus, or Galen (129 to 217 AD) [see Figure 1], was the first to significantly describe the circulatory system in living and cadaveric animals. A Roman philosopher and physician of Greek ethnicity, Galen was unable to study human cadavers because human dissection was prohibited by Roman law. Yet his descriptions, not without flaw, held authority until further discoveries were reported in the 16th century.¹ Andreas Vesalius, the founder of modern anatomy, was the first physician to perform and document a systematic human cadaveric dissection, and his publication *De Humani Corporis Fabrica* was the first to challenge Galen's findings. Vesalius revealed that Galen had worked on animals, not humans, and that the venous system was connected to the heart rather than originating from the liver as Galen had theorized—a concept that had been widely embraced for 1,500 years.² Although Vesalius's book was significant in that it disproved the Galenic theory, it lacked any detailed description of the circulatory system except where necessary to explain defects in the Galenic proposition. Rather, William Harvey [see Figure 2] has been credited with the first detailed description of the human circulatory system in his 1628 publication *De Motu Cordis*.³ Dr. Harvey's description remained authoritative until the 20th century. Unlike Galen, who described a dual parallel circulation, Harvey proposed that both the arterial and the venous circulation were a serial circuit and one unified system.

Myocardial Anatomy

The cardiac muscle, an involuntary striated muscle, is the foundation of the myocardium. The cardiac muscle has a higher mitochondrial content than other types of muscle and

Financial disclosure information is located at the end of this chapter before the references.

Figure 1 Claudius Galenus, a Roman philosopher, was well known for his comprehensive description of the circulatory system. Although his work was based on animals, it held authority for more than 1,500 years. *Claude Galien*, Vigneron lithograph by G. Engelmann, France.

can better tolerate fatigue. The cardiac muscle maintains an orientation similar to that of striated muscles and is organized into myocardial fibers. The arrangement of the myocardial fibers follows a specific pattern that is essential for efficient contractile function of the cardiac chambers. The atrial and ventricular chambers have distinct features due to differences in the embryologic origins and the functional requirements of these chambers.

ATRIAL MYOCARDIUM

The atrial myocardium consists of a superficial transverse layer and a deep layer. Although the superficial transverse layer is shared by both atrial chambers, the deep layer is distinct for each atrium. The deep layer consists of loop fibers that anchor at the atrioventricular (AV) annulus and circular fibers that surround the fossa ovalis, caval orifices, and atrial appendages. The atrial myocardium is thin—about 1 to 2 mm thick—because it is required to generate only lower gradients. The atria are mostly containment chambers that receive blood and store it temporarily before it is pushed into the ventricles, which are the main pumping chambers.

VENTRICULAR MYOCARDIUM

The ventricular chambers consist of three layers: the subepicardial layer, the middle layer, and the subendocardial layer. The middle layer is known as the ventricular myocardial band and is unique to the left ventricle.

The ventricular muscle fibers have a distinct arrangement that was described only recently by Dr. Francisco

Figure 2 William Harvey is known for publishing the most accurate anatomic description of the human circulatory system and challenged the parallel circuit description of Galen. *Guillaume Harvey*, Vigneron lithograph by G. Engelmann, France.

Torrent-Guasp.⁴ The ventricular myocardium is, in fact, a single band of cardiac striated muscle that originates at the left ventricular outflow tract (LVOT) and ends at the right ventricular outflow tract [see *Figure 3* and *Figure 4*]. In its course, the band forms a dual spiral: the inner layer forms the apical loop, and the outer layer forms the basal loop. The basal and apical loops function in coordination like a cylinder and piston. This mechanism is believed to make the process of ventricular filling an active, rather than a passive, flow-related process.⁵ Because the ventricular myocardium is a single band, the wave of contraction progresses from one end of the band to the other. While this occurs, the basal loop stiffens to form a rigid cylinder. As the wave of contraction passes through, the apical loop is pushed away, causing a suction effect in the ventricular chamber.

The wave of contraction then progresses into the apical loop, causing it to stiffen and pulling the basal loop toward the apex, thereby ejecting blood from the ventricular chamber. This sequence is illustrated in *Figure 5* and *Figure 6*. This sequential dance of the ventricular myocardium has remained one of the unsolved mysteries of cardiac anatomy for more than two millennia.⁶ In fact, the spiral arrangement of the ventricular muscle was recognized first by Galen, but the exact course and direction of the muscle fibers were unknown until their discovery by Dr. Torrent-Guasp.⁷ Understanding the arrangement of these muscle fibers is the basis of surgical ventricular restoration. The spiral arrangement of the fibers in the ventricular apex maintains the Gothic “conical” configuration of the ventricular chamber, which is mechanically more efficient than the rounded structure seen in, for example, dilated cardiomyopathy. Surgical techniques designed to restore the conical shape of the ventricle in heart failure patients are more likely to succeed than procedures that do not restore ventricular geometry.

Cardiac Electrical System

SINOATRIAL NODE

Also known as the pacemaker, the sinoatrial (SA) node initiates the contractions of the heart. The SA node is typically a collection of specialized myocytes known as nodal myocytes, which, unlike the cardiac myocytes, are stellate cells.⁸ These cells occupy the center of the node, surrounding a central nodal artery. The central location of the artery of the SA node is a unique feature of this structure. The nodal myocytes, although a type of cardiac myocyte, are primitive in phylogenetic origin and thus retain a higher rate of depolarization than any other type of myocyte, which is responsible for the overdrive of these cells in suppressing activity from other, secondary pacemaker sites [see *Figure 7* and *Figure 8*]. The SA node is a subepicardial structure located at the junction of the embryonic sinus venosus and the right atrium proper [see *Figure 9*].⁹ A plaque of

Figure 3 The ventricular myocardial band of Torrent-Guasp is a single band of ventricular myocardium that is wound in a complex spiral that maintains ventricular geometry and efficient contractility.

Figure 4 Spiral configuration of the ventricular myocardial band.

subepicardial fatty pad that occupies the groove between the terminal superior vena cava and the right atrial appendage clearly marks its location when seen intraoperatively.

ATRIOVENTRICULAR NODE

The AV node is located in the triangle of Koch on the right atrial side of the interatrial septum. The triangle of Koch is bounded by the origin of the coronary sinus, the tendon of Todaro, and the basal attachment of the septal leaflet of the tricuspid valve. The AV node is an oval structure about 8 mm long and is located just superior to the attachment of the tricuspid leaflet. The convex side of this structure faces the right atrium, whereas the concave side abuts the mitral annulus. Unlike the SA node, the AV node is composed of transitional myocytes that have a slower depolarization rate than the myocytes in the SA node.¹⁰ Importantly, the antero-inferior pole of the AV node is continuous with a specialized group of myocytes, known as the Purkinje myocytes, that in turn connects to the AV bundle.

BUNDLE OF HIS AND PURKINJE SYSTEM

The bundle of His, or AV bundle, is a continuation of the antero-inferior portion of the AV node and passes through the right fibrous trigone. Then the bundle traverses the antero-inferior portion of the perimembranous septum. This location is surgically important because it is likely to be injured during repair of ventricular septal defects.

The relation of the AV node and bundle to the aortic root is also important. Placement of valve sutures and incisions for root enlargement operations should be planned well, with close attention to the location of the membranous septum, the AV node, and the anterior mitral leaflet. Pre-operative angiograms should be reviewed to identify anomalous coronary arteries because these may preclude certain types of root enlargement options.

Immediately after traversing the perimembranous septum, the bundle of His separates into right and left fascicles. The right fascicle (otherwise known as the right bundle branch) is more discrete and rounded than the left fascicle

and courses along the right side of the interventricular septum. The structure gives off sparse branches until it reaches the papillary muscle, after which it divides into numerous fine subendocardial fascicles that permeate the ventricular musculature. The left bundle branch, on the other hand, is a flattened, sheetlike continuation of the bundle of His that has numerous fascicles that are individually sheathed. After following a short course in an apico-/subendocardial direction, this sheet splits into anterior and posterior sheets [see Figure 9]. Several fine branches, known as the Purkinje fibers, leave these sheets and form an intricate subendocardial network that encompasses the papillary muscles and ramifies through the entire ventricular chamber. The fibers are predominantly composed of Purkinje-type myocytes, which have a slower firing rate but a fast conduction pattern.

Cardiac Vasculature

ARTERIAL SYSTEM: CORONARY ARTERIES

The coronary arteries arise from the sinuses of Valsalva (SOVs) and are the first arterial branches of the aorta. The left coronary artery (LCA) arises from the left coronary sinus, which is located posteromedially, whereas the right coronary artery (RCA) typically arises from the right coronary sinus, which is located anteromedially in relation to the aortic root. The LCA, also called the left main coronary artery, averages about 2 to 3 cm in length and courses in a left posterolateral direction behind the main pulmonary artery trunk [see Figure 10, Figure 11, Figure 12, and Figure 13].

The LCA splits into the left anterior descending (LAD) and the left circumflex arteries. As the LAD runs anteriorly over the interventricular septum, it gives off the diagonal branches that supply the anterolateral wall of the left ventricle. The LAD is considered the most important surgical vessel because it supplies more than 50% of the left ventricular mass and most of the interventricular septum. The LAD has several septal perforating branches that supply the interventricular septum from the anterior aspect. The LAD extends over the interventricular septum up to the apex of the heart. Occasionally, it forms an anastomosis with the posterior descending artery (PDA), which is typically a branch of the right coronary system.

From its origin, the circumflex artery dives immediately into the AV groove and follows a clockwise course. Along its course, it gives off the obtuse marginal branches in a perpendicular fashion; these branches extend toward, but do not quite reach, the apex of the heart. The circumflex coronary artery typically terminates as the left posterolateral branch after taking a perpendicular turn toward the apex. The term *ramus intermedius* is used to designate a dominant epicardial coronary vessel that arises from the occasional trifurcation of the left main coronary artery. Some surgeons may use this term to refer either to a diagonal artery with a very high takeoff or to a very proximal obtuse marginal vessel. The ramus intermedius branch typically emerges from under the left atrial appendage, which is used as a landmark in identifying this vessel. This branch can be intramyocardial and difficult to locate at times during surgery.

Figure 5 Arrangement of the ventricular myocardial band described by Dr. Francisco Torrent-Guasp. The band is arranged to form a basal loop and an apical loop that help in the active diastolic and systolic phases of ventricular ejection.

Figure 6 Dynamic interaction of the ventricular myocardial band.

The RCA supplies most of the right ventricle, as well as the posterior part of the left ventricle. The RCA emerges from its ostium in the right coronary sinus, passes deep in the right AV groove, and then turns posteriorly toward the crux and usually bifurcates into the PDA and the right posterolateral artery. The RCA also supplies multiple right ventricular branches known as the acute marginal arteries. Occasionally, the PDA arises from both the RCA and the LCA, and the circulation is considered to be codominant. Although the source of the PDA is often used clinically to define dominance of circulation in the heart, anatomists define it according to where the SA node artery arises. The AV node artery arises from the RCA in about 90% of patients. The SA node artery arises from the proximal RCA in 50% of patients.

All of the epicardial conductance vessels give rise to a multitude of branches that traverse perpendicularly into

the ventricular wall. The rich capillary plexus offers a low-resistance system that allows arterial blood flow to increase unimpeded when oxygen demand rises. Because the myocardial vascular bed extracts oxygen at its full capacity even in low-demand circumstances, additional oxygen demand can be met only through an increase in coronary blood flow.

CORONARY VEINS

An intricate network of veins drains the coronary circulation, and the venous circulation can be divided into three systems: the coronary sinus and its tributaries, the anterior right ventricular veins, and the thebesian veins [see Figure 14]. The coronary sinus predominantly drains the left ventricle and receives 85% of coronary venous blood. It lies within the posterior AV groove and empties into the right

Figure 7 The cardiac depolarization cycle closely correlates with the mechanical contraction of the heart. The myocytes of the sinoatrial node have the highest depolarization rate of all cardiac myocytes.

atrium. The anterior right ventricular veins travel across the right ventricular surface to the right AV groove, where they form the small cardiac vein, which enters into the right atrium directly or joins the coronary sinus. The thebesian veins are small venous tributaries that drain directly into the cardiac chambers and exit primarily into the right atrium and right ventricle. Understanding the anatomy of the coronary sinus is essential for placing the retrograde cardioplegia cannula during cardiopulmonary bypass. The orifice of the coronary sinus is occasionally covered by a valve known as the thebesian valve [see Thesbian Valve, *below*].

PHYSIOLOGY OF CORONARY CIRCULATION

Under resting conditions, coronary blood flow is maintained at a fairly constant level through the process of

autoregulation. Normal coronary blood flow averages 0.7 to 0.9 mL/g of myocardium per minute, and more than 75% of the delivered oxygen is extracted in the coronary capillary bed. Any additional oxygen demand can be met only by increasing the flow rate. Unimpeded coronary blood flow for proper myocardial function is thus vital. In response to increased load, the healthy heart can increase myocardial blood flow fourfold to sevenfold. Autoregulatory mechanisms activated by a release of vasodilatory humoral factors contribute to a localized increase in blood flow. Several metabolic factors, including CO_2 , O_2 tension, hydrogen ions, lactate, potassium ions, and adenosine, contribute to this mechanism. Adenosine, a potent vasodilator and a degradation product of adenosine triphosphate (ATP), accumulates in the interstitial space and relaxes vascular smooth muscle during increased load. This results in vasomotor relaxation,

- Phase 0 = Rapid Depolarization (Increased Na^+ and Decreased K^+ Conductances)
- Phase 1 = Initial Repolarization (Decreased Na^+ and Increased K^+ Conductances)
- Phase 2 = Plateau Phase (Increased Ca^{2+} Conductance)
- Phase 3 = Repolarization (Increased K^+ and Decreased Ca^{2+} Conductances)
- Phase 4 = Resting Potential (Increased K^+ and Decreased Na^+ and Decreased Ca^{2+} Conductances)

Figure 8 Cardiac action potential schematic showing the flux of electrolytes across the cardiac myocytes during various phases of the depolarization cycle.

Figure 9 The cardiac conduction system, which consists of the sinoatrial node, the atrioventricular node, the bundle of His, and the Purkinje fibers. All these cells are various types of specialized myocytes.

coronary vasodilatation, and increased blood flow. Another important substance is nitric oxide (NO) produced from the endothelium. In the absence of endothelium, coronary arteries do not autoregulate, suggesting that the mechanism for vasodilatation and reactive hyperemia is endothelium dependent.

During systole, the intracavitary pressures generated within the left ventricular wall exceed intracoronary pressure, and blood flow is impeded. Hence, approximately 60% of the coronary blood flow occurs during diastole. During exercise, increased heart rate and reduced diastolic time can compromise flow time, but this effect can be offset by the vasodilatory mechanisms of the coronary vessels. Fixed coronary occlusion can significantly impair the compensatory mechanisms that maintain coronary blood flow while the heart rate is elevated. Our knowledge of this phenomenon makes it possible to uncover underlying occult coronary disease during exercise-induced stress tests.

Fibrous Skeleton of the Heart

A complex framework of connective tissue composed of collagen lies in a plane somewhat parallel to the AV groove and forms the anchoring foundation of the heart

[see Figure 15]. This framework has been referred to as the fibrous skeleton and consists of membranous and tendinous structures. Essentially, the annuli of all the cardiac valves abut each other, forming this complex structure. The fibrous skeleton of the heart was not recognized by early anatomists because the annulus and trigones of the mitral apparatus were presumed to be separate structures. The mitral, tricuspid, and aortic annuli are intimately associated.

The mitral and tricuspid annuli lie in a similar plane, whereas the aortic annulus is slightly anterosuperior to the mitral orifice and faces forward. The pulmonary annulus is distant from the main components of the fibrous skeleton and is attached to the aortic annulus by the conus ligament, which forms an integral component of the infundibulum. Although the primary function of the fibrous skeleton is to anchor the leaflets of the cardiac valves, it also acts as a physiologic barrier that prevents electrical continuity between the atrium and ventricles. As noted above, in normal circumstances, the bundle of His is the only structure that carries electrical activity from the atrium to the ventricle and penetrates through the fibrous skeleton of the heart. The fibrous skeleton is also the anchor point of the ventricular myocardial band.

Figure 10 Anatomy of normal coronary artery vasculature.

Understanding the structural continuity of the fibrous skeleton is essential to understanding the three-dimensional relations of the cardiac valvular structures. The aortic valve occupies the central location and functions as a reference point during echocardiography. The aortic annulus, known as the annulus fibrosis, is the foundation of the aortic root, onto which the valve leaflets, interleaflet triangles (ILTs), LVOTs, and SOVs converge. The fibrous skeleton has remarkable tensile strength that anchors the aortic root to the LVOT, lest the aorta be torn from the point of its left ventricular attachment by the tremendous accelerative forces generated by ventricular systole. Derangements of fibroskeletal integrity, such as loss of aortomitral continuity, are noted in congenital heart defects such as tetralogy of Fallot and are pathognomonic of conotruncal anomalies.

Cardiac Valves

AORTIC VALVE

The aortic valve guards the outlet of the LVOT and prevents aortic blood from returning to the ventricle during diastole [see Figure 16]. The valve is similar in construction to the pulmonary valve and consists of three cusplike leaflets [see Figure 17 and Figure 18]. Although the aortic valve is located in a high-pressure zone, the leaflet structures are not as strong as the mitral leaflets. This is because the maximum pressure forced against the closed leaflets is typically the diastolic aortic pressure, which is considerably lower than the maximal systolic pressure forced against the closed mitral valve. Although anatomically the aortic valve is considered to consist of three semilunar cusps and the

Figure 13 The right coronary artery as seen during cardiac catheterization. Arrow marks the right main coronary artery.

Figure 12 The left anterior and circumflex coronary arteries as seen during a routine cardiac catheterization. Large arrow marks the left anterior descending and small arrow marks circumflex coronary artery.

aortic annulus, this description discounts the fact that the aortic valve and the aortic root are a single, complex structure (which is described in detail in a subsequent section of this chapter).

The aortic semilunar cusps are essentially extensions of the endocardium and attach at the base to the annulus

fibrosus. The free margin of the aortic cusp is slightly thick and condenses into a nodular structure at the center, known as the nodulus Arantii. The aortic commissures are the highest point between two adjacent semilunar valves at the attachment of the annulus fibrosus. Because of the curvilinear attachments of the semilunar valves, the annulus fibrosus takes the shape of a coronet rather than a simple ring. Understanding the coronet shape of the annulus fibrosus is essential during valve replacement surgery because anchoring sutures for the aortic valve should be placed in the fibrous tissues of the annulus rather than the subannular tissues, which are relatively weaker. The aortic valve cusps are named according to the origin of the coronary arteries, such as the right coronary cusp, anterior in location; the left coronary cusp, left and posterior in location; and the noncoronary cusp, right and posterior in location.

MITRAL VALVE

The mitral valve guards the left AV orifice, which lies in a vertical plane that is tilted about 45° to the coronal plane. The mitral valve is intimately connected to the tricuspid and aortic valves through the fibrous skeleton [see Figure 19]. The mitral annulus has certain distinct features that make it physiologically functional. The mitral annulus is not a true circular structure but, rather, a flattened circle. When viewed from the left atrial aspect, this flattened aspect of the circumference extends from about the 10 o'clock to the 2 o'clock position [see Figure 20]. The remaining aspect of the annulus has a more circular shape. The junction between the flattened and circular aspects of the annulus is marked by dense concentrations of fibrous tissue on either side known as the trigones and forms an integral anchor point of the fibrous skeleton of the heart. The flattened aspect of the mitral annulus, in conjunction with the commissure between

Figure 14 The coronary venous system, which drains either directly into the cardiac chambers or via the coronary sinus.

the left and noncoronary aortic cusps, forms a triangular area beneath the aortic valve that fades into the anterior leaflet of the mitral valve. This is defined as the aortomitral continuity, or the subaortic curtain, and it is intimately related to the LVOT, the intercommissural triangle of the aortic valve, and the anterior mitral leaflet [see Figure 20]. This

location of the anterior mitral leaflet places it between the left ventricular inflow and outflow tracts, making the anterior leaflet an interventricular aortic baffle. Changes in the position and flexibility of the annulus spanning the anterior mitral leaflet can push the mitral valve into the LVOT; this phenomenon, commonly known as systolic

Figure 15 The fibrous skeleton of the heart.

anterior motion, can impede the ejection of blood from the ventricular cavity during systole.

The two mitral valve leaflets form a bicuspid valve with a deep central cleft resembling that of a miter (a bishop's headdress), from which the valve takes its name. Although, for clinical purposes, the two cusps are considered separate,

in reality, the mitral valve is a single circumferential curtain with multiple indentations along the edge, two of which are quite prominent and are designated as the left (postero-medial) and right (anterolateral) commissures. These commissures receive anchoring attachments from the papillary muscles via numerous chordae that fan out into the edges

Figure 16 The cardiac valves in normal anatomic configuration.

of the anterior and posterior mitral leaflets [see Figure 21]. In addition, two medium-sized clefts are located along the posterior leaflet that divide it into three prominent scallops, labeled P1, P2, and P3 from left to right, on the basis of the surgeon's view of the mitral valve through the left atrium. The corresponding opposing aspects of the anterior leaflet are named A1 through A3, although no prominent clefts are identified.¹¹ This designation is essential for surgeons to describe and plan mitral reconstructive techniques. The location of the posterior mitral clefts varies significantly, and it is crucial to recognize them clinically for successful mitral repair surgery.

The posterior mitral leaflet includes all valvular tissue that spans the circular aspect of the mitral annulus, extending from one commissure to the other, and has a much broader attachment than the anterior leaflet. Each of the posterior leaflet's three scallops has a finely serrated edge that receives attachments from the chordae, which also extend to the ventricular aspect of the scallop. This area, which receives most of the chordal attachments, is known as the rough zone, which becomes more translucent as one progresses from the free margin to the annular base. The translucent clear zone is devoid of any chordal attachments.

The mitral annulus tends to calcify with age because of the shearing forces that occur over time. This calcification may be obvious on chest radiograms. Calcification of the mitral annulus is a relative contraindication for mitral valve surgery because it confers a high risk of mechanical AV disruption, which is potentially fatal. Also, calcification makes the annulus less deformable, lowering the odds of successful mitral valve annuloplasty. Because the posterior mitral leaflet has a wider area of attachment than the anterior leaflet, a more extensive chordal anchoring to the papillary muscle is associated with the posterior leaflet. The entire complex involving the posterior mitral leaflet, chordal

attachments, and both papillary muscles maintains the ventricle's conical, rather than globular, shape. Surgeons typically tend to spare the entire posterior mitral leaflet and minimize any resection during valve replacement so that the ventricular geometry is maintained; this practice has been credited with reducing the detrimental long-term ventricular remodeling that occurs when all chordal attachments are resected.

TRICUSPID VALVE

The tricuspid valve is integrally related to the mitral valve and the fibrous skeleton and is best described as an entire complex, similar to the mitral valve, composed of the valvular leaflets, the chordae tendineae, the papillary muscles, and the annulus [see Figure 22]. The right AV orifice is the largest valve orifice in the heart and is quite ill-defined. Unlike the mitral orifice, the tricuspid orifice is indistinct, and the attachments of the leaflets are the only landmarks of the separation between the right atrial and ventricular tissue. In the absence of leaflet attachments, the tricuspid annulus is hard to define, especially because of the interruption of and variations in the quantity of collagenous tissue in the annulus itself.

The tricuspid valve has three leaflets, known as the septal, anterior, and posterior leaflets. Like the mitral valve, the tricuspid valve is a continuous veil of tissue separated by indentations that demarcate the leaflets. Further intermediary indentations divide the posterior leaflet into three scallops, whereas the anterior and septal leaflets have a marginally distinct cleft. The anterior leaflet of the tricuspid valve is the largest leaflet, and the septal leaflet is the smallest. The attachment of the anterior and septal leaflets extends onto the membranous septum at the anteroseptal commissure. In contrast, the posterior leaflet is entirely flanked by atrial and ventricular myocardium. The attachment

Figure 17 The aortic valve. This valve is composed of three semilunar valve cusps (also known as leaflets) and the aortic annulus.

of the septal leaflet spans the triangle of Koch, which contains the AV node. Any sutures placed in the annulus of the tricuspid valve are likely to injure the AV node; thus, in tricuspid valve replacement, the anchoring sutures are

placed in the leaflet tissue itself rather than the septal annulus. It is important that the septal leaflet not be completely resected in tricuspid valve replacements. For tricuspid repairs, only incomplete annuloplasty rings are used;

Figure 18 The aortic valve—surgeon's view and relation to surrounding cardiac structures.

Figure 19 The mitral valve and its relation to surrounding cardiac structures.

Figure 20 The mitral valve—surgeon's view, including segments of the valves and relation to the subaortic curtain.

Figure 21 Attachment of the mitral valve leaflets with chordae and papillary muscles (front and side views). The entire mitral complex takes on the appearance of a parachute held by several chordae.

these rings are designed with a gap that spans the septal valve leaflet to avoid suture placement in the triangle of Koch.

The annular attachment of the tricuspid septal leaflet is more intimately associated with the mitral annulus and central fibrous tendon than the attachments of the anterior and posterior leaflets. Thus, the septal leaflet is less prone to stretching or deformation. This information is important in understanding the mechanism of tricuspid regurgitation due to annular dilation. Whereas the anterior leaflet partly extends over the membranous septum and is somewhat restricted to stretching, the posterior leaflet extends along the free wall of the right ventricle and is more prone to stretching in tricuspid annular dilation. Typically, for every unit increase in the basal circumference of the anterior leaflet, there is a two-unit increase in the attachment of the posterior leaflet, whereas the septal attachment remains constant. Thus, in sizing annuloplasty rings, the gap in the ring is chosen such that it corresponds to the width of the basal attachment of the septal leaflet because this component of the tricuspid valve is least altered by conditions that make annuloplasty necessary.

PULMONARY VALVE

The pulmonary valve guards the outlet of the right ventricle and is located away from the three other structural cardiac valves. The pulmonary valve, like the aortic valve, is a semilunar valve composed of three cusps. The cusps are located in left anterior, right anterior, and posterior orientations. As in the aortic valve, the cusps of the pulmonary valve are a derivation of the endocardial fold. The central

part of the leaflets is the lamina fibrosa, which is a condensation of collagenous tissues. The lamina fibrosa is of varying thickness but is typically more prominent at the edge and the base of the leaflet, where it merges with the pulmonary annulus. The nodulus Arantii and the sinus configuration of the pulmonary artery are very similar to those of the aortic valve. Except for differences in pressure-handling characteristics, the pulmonary valve is quite similar to the aortic valve. This remarkable similarity is of particular significance to surgeons because it makes the pulmonary valve usable as an autograft in the aortic position (Ross procedure). The relation of the base of the pulmonary valve and annulus to the ventricular septum is important because the first septal perforator from the LAD is closely related to this valve and can be injured during harvest of the valve for autograft purposes.

THEBESIAN VALVE

About 300 years ago, Adam Thebesius described the valve guarding the ostium of the coronary sinus, now known as the thebesian valve [see Figure 23]. Although it remained clinically insignificant for centuries, the development of innovations that require intervention via the coronary sinus has increased cardiologists' and surgeons' interest in this structure.¹² The thebesian valve is a remnant of the SA valves and can interfere with the cannulation of the coronary sinus for retrograde cardioplegia during cardiac surgery. Studies have shown that thebesian valves exist in anywhere between 70 to 80% of normal adult human hearts.^{13,14} These valves vary significantly in composition, ranging from membranous to muscular.¹⁵

Figure 22 The relation of the tricuspid and pulmonary valves.

EUSTACHIAN VALVE

The eustachian valve is a fold of atrial remnant that guards the orifice of the inferior vena cava. It plays an important role in fetal circulation by acting as a baffle to direct returning oxygenated blood from the vena cava toward the atrial septum into the fetal systemic circulation. Typically, after birth, this valve reduces to a thin, nonfunctional ridge that is of no consequence. However, the eustachian valve occasionally remains prominent and is not reabsorbed, resulting in a persistent baffle.¹⁶ This may occasionally pose difficulties in deploying drainage cannulas in the inferior vena cava for cardiopulmonary bypass. Also, a prominent eustachian valve can be misidentified as the lower edge of an atrial septal defect and inadvertently included in the closure suture line. This may result in all venous return from the inferior vena cava being directed through the atrial septal defect into the systemic circulation, causing severe cyanosis.

Cardiac Valve Adjuncts

PAPILLARY MUSCLES

The left ventricle has two distinct papillary muscles that bear important clinical significance because of their involvement in acute myocardial infection and ischemia. The anterolateral papillary muscle arises in the free wall of the left ventricle that lies behind the costochondral

junctions, whereas the posteromedial papillary muscle arises from the inferior wall of the left ventricle, close to the ventricular septum. It should be noted that no papillary muscle arises from the septal area. The papillary muscles give out several chordae that fan out and attach to the mitral leaflets. Each papillary muscle contributes chordal attachments that span the corresponding commissure and anchor both the anterior and posterior leaflets. The papillary muscle–chordal complex connects the mitral leaflets and ventricular myocardium and functions in a symbiotic role for both structures. Although the complex tethers the mitral valve and prevents leaflets from prolapsing into the atrium, rendering the valve incompetent during high-pressure ventricular systolic forces, the complex also maintains the conical shape of the left ventricular chamber by anchoring it to the fibrous skeleton via the valves, which is essential for efficient ventricular contraction. The right ventricle has a prominent anterior papillary muscle that merges with the moderator band and anchors the anterior leaflet. Posterior to the moderator band are several small papillary muscles that tether the posterior and septal leaflets.

In acute myocardial infarction involving the inferior ventricular blood supply, the posterior papillary muscle can necrose and be avulsed off the attachment, resulting in an acutely incompetent mitral valve. This usually constitutes a surgical emergency that necessitates replacement of the mitral valve.

Figure 23 The thebesian valve, which guards the orifice of the coronary sinus.

CHORDAE TENDINAE

Chordae tendineae are collagenous cords that arise from the tip or apical third of the papillary muscle and are attached to some aspect of the leaflet.^{17,18} Chordae are classified as follows:

1. Fan-shaped chordae arise from the tips of papillary muscles, are flat, and fan out to the commissures and clefts.
2. Rough zone chordae are strong single chords attached to the free margin and the underside of the coapting surface of the leaflets. They are the chordae most commonly involved in chordal rupture and are a common cause of mitral regurgitation because they are subject to higher tensile forces.
3. Free-edge chordae are long, single chordae that attach only to the free edge of the leaflet at the midpoint of the scallops.
4. Deep chordae are attached to the undersurface of the leaflet in the clear zone.
5. Basal chordae are of variable shape and insert near the basal attachment of the leaflets. They play an important role in maintaining ventricular geometry and are spared in valve replacements.

AORTIC ROOT

Structure of the Aortic Root

Because of the close relation among the aortic valve, the aortic annulus, and foundation structures, the aortic root is considered a single entity with these various components: SOVs, sinotubular ridge, annulus fibrosus, aortic valve leaflets, ILTs, and coronary ostia [see Figure 24]. Each of these structures interacts significantly with the others, and together they are responsible for the performance of the aortic valve. Although one may consider the cusps alone to form the true aortic valve, the proper function of the semilunar cusps is heavily dependent on the integrity of the entire aortic root. By definition, the aortic root extends from the nadir of the hinge points of the valve cusps to the sinotubular junction. The aortic root has several key functions¹⁹:

- Supports the leaflets of the aortic valve
- Dynamically adapts to accommodate systolic efflux of blood from the left ventricle
- Directly influences the mechanism of leaflet function

The SOV, first described by Italian physician Antonio Maria Valsalva,²⁰ is bounded inferiorly by basal attachments of each cusp and is limited superiorly by the sinotubular ridge. The upper limit of the SOV extends more superiorly than the free cuspal border of the valve leaflets.^{21,22} The SOV has more collagen at its base than in the upper part and an increasing density of elastic lamellae superiorly. The coronary ostia originate at the superior aspect of the sinus. The SOV plays a functionally significant role in the valvular mechanism [see Aortic Valve: Closure Mechanism, below]. The midportion of the SOV can be twice the diameter of the ascending aorta, whereas the thickness is 50% that of the ascending aorta and 25% that of the sinotubular ridge. The sinotubular ridge is the circumferential thickening of the aortic wall at the junction between the sinusal and tubular portions of the aorta and is predominantly elastic. The elasticity of the sinotubular ridge allows a 16% increase in diameter when necessary and is manifested by splaying of the commissures during systole.²³ The annulus fibrosus is the collagenous condensation at the point of attachment of each leaflet; it forms the support structure of the aortic root and is the most important component of the fibrous skeleton. The annulus has the shape of a coronet rather than a circle. An imaginary circle connects the nadir points of the annulus fibrosus/semilunar attachments and is termed the “basal ring.” This ring serves as the proximal demarcation line between the LVOT and the aortic root.

The annulus fibrosus is a rigid structure and does not vary in dimension during different phases of the cardiac cycle. However, the annulus deforms significantly during ventricular contraction, with the basal aspect of the coronet remaining constant in shape, whereas the points of the coronet (commissure) move outward during systole. During systolic expansion, the sinotubular ridge, along with the commissural points, pulls the free edges of the cusp taut²⁴ to form a straight line. This ensures the laminar flow of blood and

Figure 24 Structure of the aortic root. This longitudinal section shows the root's relation to surrounding structures.

helps create the sinusal vortex, which prevents apposition of the leaflets against the wall. Preventing leaflet apposition is important for valve closure and ensuring unimpeded coronary blood flow.

Dynamic Interaction of Aortic Root

Aortic valve: opening mechanism Contrary to the traditional belief that pressure from the ventricle forces the aortic valves to open passively, recent flow dynamic assays have shown that the opening of the aortic valve is an active process that begins even before the ejection of blood [see Figure 25].²⁵ Commissural displacement occurs just before ventricular ejection. This displacement, along with expansion of the sinotubular ridge, begins to pull the cusps of the aortic valve apart before enough ventricular pressure is generated to force them open. The ILTs play an important role in initiating commissural displacement before ventricular ejection commences.^{26,27} The ILTs are the layers of tissue between the commissures and are attached to the LVOT. An ILT is composed of circularly oriented layers of collagen and receives muscular attachments that may extend from the LVOT. The contraction of these muscle fibers initiates a tilting movement of the ILT outward when ventricular systole begins, well before enough intracavitary ventricular pressure is generated. Furthermore, the movement of blood against the inferior surface of the ILT further enhances the

outward displacement of the commissures that helps open the aortic valve leaflet. Root compliance contributes to aortic root dilation just before leaflet opening and thus helps pull closed leaflets apart, reducing friction at commissures [see Figure 26]. A minimal pressure gradient of approximately 2 mm is sufficient to spring leaflets open as systole is initiated. In a normal root, the effective valve orifice area progressively increases with an increase in gradient. This dynamic compliance is impaired in stiff or calcified roots. Aortic leaflet opening is thus a very controlled and complex process that is actively assisted by the commissure.

Aortic valve: closure mechanism The SOV plays an important role in initiating aortic valve closure. The sinus acts as a vortex generator. During systolic ejection, a small portion of the blood is diverted into the SOV and coronary ostia by the sinotubular ridge. This results in a laminar circular vortex of blood in the sinus that creates an equalizing and opposing pressure on the outer side of the valve cusps.²⁸ The valve cusp is thus floating in a zone of no pressure created by the opposing forces of the blood flowing in the luminal aspect of the aortic root and the vortex force on the sinusal aspect. This minimizes the valve stress on the leaflets during systole. As the systolic cycle progresses, the ejection velocity of the luminal blood diminishes, and the inward force of the vortex becomes unimpeded, forcing the valve

Figure 25 Dynamic interaction of the aortic root.

cuspid medially, thereby initiating closure. Typically, only 4% of blood volume regurgitates in normal aortas. When the SOV is calcified or absent (as in graft replacements of the aortic root), this mechanism is impaired, and as much as 25% of ejected volume must be captured by the leaflets to close the valve. Closing the valve is associated with significant leaflet cusp bending and shear, which could lead to accelerated degeneration.²⁹

As noted, there is a complex interaction of the various aspects of the aortic root that ensures a smooth laminar flow across the aortic valve. Any mechanism or disease process, such as calcification or replacement of the elastic tissue with a rigid structure (such as a prosthetic graft), could derange the active mechanism in aortic leaflet opening/closing, leading to higher shear stresses and accelerated valve degeneration.

Figure 26 Mechanism of aortic valve leaflet opening. LV = left ventricular.

Cardiac Chambers

ATRIAL CHAMBERS AND APPENDAGE

The right atrium lies slightly anterior and to the right of the left atrium and forms the right heart border. The superior and inferior venae cavae open at the superior and inferior parts of the right atrium. The inner aspects of the right atrium contain a smooth posterior area derived from the sinus venosus remnant and a trabeculated anterior aspect derived from the true right atrium. The demarcation between the two embryologic components is marked internally by a vertical ridge known as the crista terminalis, which corresponds to a longitudinal groove on the outside, the sulcus terminalis. The right atrial appendage projects from the anterior aspect of the right atrium just below the entry of the superior vena cava and overlies the proximal RCA and the lateral aspect of the aorta.

VENTRICULAR CHAMBERS

Right Ventricle

The right ventricle is the most anterior chamber of the heart, and the convex anterior surface is separated from the chest wall only by the pericardium. This chamber is likely to be injured in penetrating wounds to the chest. The right ventricular wall is much thinner, varying between 3 and 5 mm in thickness. In cross section, the right ventricle is a crescent-shaped chamber into which the interventricular septum bulges [see Figure 27]. Internally, the right ventricle has an inflow tract guarded by the tricuspid valve. The chamber has numerous trabeculae, which are simply muscular ridges that meld with the papillary muscles. The moderator band, otherwise known as the septomarginal trabecula, is a prominent trabecula that extends from the anterior papillary

Figure 27 The ventricular chambers—cross-sectional and longitudinal cartoon showing the significant difference between the left and right ventricular chambers.

muscle to the septum and contains the right bundle branch. The outflow tract is known as the infundibulum and extends into the pulmonary orifice. The infundibulum is easily identified on the inside of the ventricular chamber at the level of the supraventricular crest. The infundibulum is a remnant of the bulbus cordis and maintains a foundation for the pulmonary annulus.

Left Ventricle

The left ventricle is a sturdy conical chamber that is three times thicker than the right ventricle. The left ventricle forms the left border of the heart. The base of the ventricle is formed by the left AV orifice and the LVOT. Both the left ventricular inflow and outflow tracts face the left ventricular apex, which efficiently directs blood flow toward the ventricular chamber. Transverse section of the left ventricle reveals a circular shape, unlike the crescent shape of the right ventricle. The inside of the left ventricular chamber has trabeculae similar to those in the right ventricle but much larger. The two papillary muscles form important landmarks within the left ventricle and have been described [see Papillary Muscles, *above*].

Intracardiac Structures

INTERATRIAL SEPTUM

The septal wall has more features and landmarks that are recognizable from the right side than from the left side [see Figure 28]. The fossa ovalis is the most prominent oval

depression in the lower part of the interatrial septum. The base of this depression is the remnant of the original septum primum. The limbus is the prominent superior and posterior margin of the fossa ovalis and marks the inferior border of the septum secundum. Occasionally, the limbus is not a complete fusion but has a slitlike opening that extends into the left atrium; this opening is known as a patent foramen ovale. The prevalence of patent foramen ovale is as high as 30% in adults. Although usually of no clinical consequence, it is believed to occasionally allow thrombus from the deep veins that extend into the right atrium to migrate into the left-sided circulation, causing a “paradoxical embolus.”

Anteroinferior to the fossa ovalis lies the right AV orifice. At this junction is a triangular zone known as the triangle of Koch. The septal attachment of the tricuspid leaflet, the coronary sinus orifice, and the tendon of Todaro—a subendocardial ridge that extends from the edge of the right fibrous trigone to the inferior vena cava orifice—bound this triangle. This triangle contains the AV node and the proximal aspect of the bundle of His.

INTERVENTRICULAR SEPTUM

The interventricular septum is a curved structure that bows into the right ventricular cavity. The structure of the interventricular septum is diverse, varying from membranous to muscular in different locations. Therefore, ventricular septal defects are broadly classified (according to their location) as perimembranous or muscular. The left ventricular side is quite smooth, with fine trabeculations, whereas

Figure 28 The interatrial septum. The figure depicts the fossa ovalis and its relation to surrounding structures. One of these, the triangle of Koch, is an important landmark to recognize because the atrioventricular node is located at the apex of this triangle.

the right size of the muscular septum is heavily trabeculated. The left side of the interventricular muscular septum has a smooth outlet portion that is devoid of trabeculations. The trabeculated sinus portion below the mitral valve is the inlet septum. The A3 component of the mitral valve, the right aortic cusp, and part of the noncoronary aortic cusp bear attachments to the left side of the interventricular septum. The septal aspects of the right ventricle are classified as the inlet, trabecular, and outlet portions. The inlet and trabecular portions are similar to the left ventricular surface. However, the outlet septum has three components, the conal or infundibular septum being the most prominent. The conal septum separates the pulmonary valve from the tricuspid and aortic valves. The infundibulum extends onto the free right ventricular wall, forming the parietal band, most commonly referred to as the crista supraventricularis because it extends above the ventricles. Defects in this portion of the ventricular septum are called supracristal ventricular septal defects [see Figure 29].

The membranous septum is the fibrous aspect of the septum that separates the LVOT from the right ventricle and right atrium. As described before, the attachment of the anterior and septal leaflets of the tricuspid valve extends onto the membranous septum, separating it into a ventricular and atrial component on the right side. The membranous septum has an interventricular and an AV component.

The AV septum is a distinct area of the cardiac septum that separates the left ventricle from the right atrium. This separation occurs because the septal attachment of the mitral valve is shifted more toward the atrial chamber than

the tricuspid valve. This septum has both a membranous and a muscular component, and the AV node lies in the junction between the two components. The AV septum is located within the triangle of Koch.

The Pericardium

The pericardium consists of two opposing serous lined surfaces separated by a fluid layer that allows unimpeded movement of the heart during contractions [see Figure 30]. The outer layer is the fibrous pericardium, and the inner layer is the serous pericardium. The outer, fibrous layer is attached to the tendinous portion of the diaphragm inferiorly, whereas the superior aspect is continuous with the great vessels of the heart. The fibrous pericardium is separated from the chest wall by the anteromedial aspects of both lungs, except for a small portion at the left of the left fourth and fifth costochondral junctions. All major vessels entering or leaving the heart, except the inferior vena cava, receive investing extensions from the fibrous pericardium.

The serous pericardium has parietal and visceral components. The parietal lining is closely apposed to the inner surface of the fibrous pericardium, whereas the visceral lining is otherwise known as the epicardium and closely blends with the epicardial musculature of the heart. The complex investment of the serous pericardium around the great vessels and the surface of the heart results in the formation of two important recesses in the pericardial cavity. One is the oblique sinus, which extends posteriorly and leftward

Figure 29 The interventricular septum. The figure depicts the inlet, muscular, perimembranous, and supracristal types of ventricular septal defect.

Figure 30 Drawing of the structure of the heart and its major vessels. The pericardium forms an investing layer around the heart and has two distinct recesses that function as important landmarks for surgeons: the transverse and oblique sinuses.

from the left ventricular apex behind the AV groove and posterior wall of the left atrium and terminates at the reflection between the left and right superior pulmonary veins. The other important recess is the transverse sinus, which extends behind the aortic and pulmonary trunks and lies in front of the left and right atria and the superior vena cava. These two sinuses provide landmarks and guidance during the placement of ablation devices for the surgical treatment of atrial fibrillation.

5 THE ENDOCRINE SYSTEM: PITUITARY AND ADRENAL GLANDS

Haggi Mazeh, MD, Iddo Paldor, MD, and Herbert Chen, MD, FACS

Pituitary Gland

The pituitary gland, or hypophysis, is a unique endocrine-functioning part of the central nervous system (CNS). Located inside the sella turcica, it is separated from the rest of the CNS by its physiologic location outside the blood-brain barrier. The function of the gland is regulated by higher-order nervous systems, mainly the hypothalamus, which has synaptic and hormonal connections to the pituitary gland. This regulation may be a positive (i.e., stimulatory) effect, a negative (i.e., inhibitory) effect, or both. The pituitary gland governs hormonal secretion from all endocrine organs in the body and has elaborate feedback loops from all of these organs.

The hypophysis is, in fact, a combination of two separate hormone-secreting glands. These glands differ in embryologic development, in the origin of the hormones secreted, in function, and in the form of trigger for hormonal secretion.

EMBRYOLOGY AND DEVELOPMENT

The posterior hypophysis, or neurohypophysis, is derived embryologically from downward evagination of the neuroectoderm in the floor of the third ventricle. It remains functionally an extension of the hypothalamus, which lies superior to it, and the hormones secreted from it are synthesized in the neurons of the hypothalamus. These hormones—oxytocin and antidiuretic hormone (ADH)—are then transferred through axonal transport to the posterior hypophysis, where they are secreted into the systemic blood circulation. Therefore, the hormonal function of the neurohypophysis is not part of the portal system, described later in this chapter.

The anterior hypophysis, or the adenohypophysis, is derived embryologically from the epithelial ectoderm of the oropharynx, known as the stomodeum. This evagination occurs in the fourth week of development to form the Rathke pouch. During the sixth week of development, the anterior hypophysis develops to be anatomically separated from the oropharynx (the other major derivation of the same epithelial ectoderm) by the bones in the anterior skull base, mainly the sphenoid bone. The mature derivatives of the Rathke pouch are the anterior lobe of the hypophysis, the pars intermedia, and the pars tuberalis.^{1,2}

ANATOMY

The pituitary gland lies at the base of the skull, in the medial part of the middle fossa [see *Figure 1*]. It is encompassed by the bony sella turcica, which is made up of the tuberculum sellae in the anterior aspect and the dorsum sellae in the posterior aspect.

The tuberculum sellae is the posteromedial part of the lesser wing of the sphenoid bone. Hanging over the pituitary fossa in its anterolateral part are the paired anterior clinoid processes.

The dorsum sellae, the posterior bony part of the sella turcica, is the anterosuperior continuation of the clivus. The clivus is the posterior part of the sphenoid bone. Hanging over the pituitary fossa in its posterolateral aspect are the paired posterior clinoid processes.

The pituitary gland is separated superiorly by the sellar diaphragm, a dural fold that is pierced by the pituitary stalk. In close relation to the pituitary gland are the cavernous sinus on each lateral aspect, the sellar diaphragm, and the optic chiasm above it.

The pituitary gland is, in fact, an inferior protrusion of the hypothalamus, which is part of the diencephalon. It receives both neural and hormonal regulatory inputs from the hypothalamus. The pituitary gland is also subject to regulation by inputs from other areas of the brain, including autonomic, limbic, and even paracrine inputs from other cells within the gland itself.^{3,4}

The adenohypophysis is the rostral part of the gland. It is made of three lobes. The pars distalis, the largest part of the gland, is in the anterior part of the gland. The posterior pars tuberalis is the part of the adenohypophysis located around the entry zone and the inferior part of the infundibular stalk. The pars intermedia is a thin epithelial layer separating the pars tuberalis from the pars distalis.

The neurohypophysis is the posterior part of the gland. It does not function as a regular hormone-secreting gland in that the stimulus for release of its hormones is not an endocrine stimulus. The neurohypophysis is made of axonal projections arising from the paraventricular and supraoptic nuclei of the hypothalamus. The neurohypophysis is made of two parts: the pars nervosa and the infundibular stalk. The pars nervosa is the main functional part of the neurohypophysis. It is where the projections from the hypothalamus terminate and release their hormonal secretions into the general circulation via capillaries of the hypophyseal circulation, described later in this chapter. This secretion is not part of the pituitary portal system. Other than these axons, the pars nervosa is composed of pituicytes, which are glial cells that closely resemble the astrocytes of other parts of the CNS. The infundibular stalk is the site of entry for the hypothalamic projections and forms the neural (rather than portal) bridge between the hypothalamus and the hypophysis.⁵

The two parts of the hypophysis—the neurohypophysis and the adenohypophysis—are separated by a thin layer known as the CNS skin. Some refer to a middle lobe, which has significant roles in other species. The main function of the middle, or intermediate, lobe in humans is the secretion of melanocyte-stimulating hormone, as well as secretion of

Financial disclosure information is located at the end of this chapter before the references.

pro-opiomelanocortin (POMC). There is little known clinical significance of this lobe in humans. POMC serves as a precursor for some of the other hormones in other lobes of the hypophysis. Some refer to this lobe as part of the anterior lobe.⁶

Blood Supply and the Portal System

The blood supply to the pituitary gland is derived mainly from the internal carotid artery (ICA) and its main branches [see Figure 2].

The inferior hypophyseal artery arises from the ICA in its course through the cavernous sinus (i.e., it is a branch of the cavernous ICA). The inferior hypophyseal artery supplies the lower part of the infundibulum and the majority of the neurohypophysis.

The superior hypophyseal artery gives rise to the pituitary portal system, one of only two such systems in the human

body. This artery arises from the first part of the supraclinoid ICA. It supplies the lower part of the hypothalamus, where it receives projections from neurosecretory cells in the parvicellular portion of the hypothalamus. This first capillary bed occurs in the anterior part of the infundibulum, known as the median eminence. These capillaries are the site of presentation of hypothalamic neurosecretory factors, which serve as modulators of hormonal release. After receiving these factors, the capillaries reemerge as long portal veins, which descend along the anterior aspect of the pituitary stalk to reach the pars distalis in the anterior hypophysis. In this area, the long portal veins give rise to a second capillary bed, which supplies the anterior hypophysis. It is through this capillary bed that the regulatory hypothalamic hormonal inputs to the adenohypophysis are supplied.⁷

Figure 2 The pituitary blood supply, venous drainage, and portal system. ACTH = adrenocorticotrophic hormone; ADH = antidiuretic hormone; FSH = follicle-stimulating hormone; GH = growth hormone; LH = luteinizing hormone; OCT = oxytocin; PRL = prolactin; TSH = thyroid-stimulating hormone.

There are other, smaller arteries supplying the gland. The infundibular artery arises from the posterior communicating artery.⁸ On the anterior aspect, the prechiasmal artery arises from the ophthalmic artery.

The capsular artery and the artery to the inferior cavernous sinus arise from the cavernous part of the ICA. These arteries anastomose with each other and create a vascular network supplying the pituitary gland. There are two arterial circles surrounding the gland: the circuminfundibular anastomosis incorporates the arteries from above the pituitary, that is, the superior hypophyseal, infundibular, and prechiasmal arteries, and the inferior hypophyseal arterial circle is created by the inferior hypophyseal artery, the capsular artery, and the artery to the inferior cavernous sinus.

The part of venous drainage through the long portal veins, part of the portal system, has been described earlier. Venous drainage of the anterior pituitary gland is through the short portal and adenohypophyseal veins. Drainage of the posterior pituitary is through the neurohypophyseal veins. Both of these venous systems drain to form the common lateral hypophyseal veins, which drain into the cavernous sinus.

NORMAL PHYSIOLOGY

Neurohypophysis

The endocrine function of the hypophysis is governed by many inputs from higher-order neuronal elements [see Figure 3]. The most significant modulator of this hormonal secretion is the hypothalamus. The neurohypophysis secretes two hormones. Oxytocin is involved in uterine contractions and other childbearing and breast-feeding functions. ADH is involved in modulation of water retention and blood pressure. These hormones are synthesized in hypothalamic nuclei and released in the neurohypophysis by axonal projections from these hypothalamic nuclei.⁹

The adenohypophysis secretes six hormones, which are discussed in detail in the following sections. In general terms, three of these hormones are released primarily in response to hypothalamic stimulation: adrenocorticotrophic hormone (ACTH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH). Two adenohypophysary hormones are subject to dual hypothalamic modulation. That is, they are under both hypothalamic stimulation and hypothalamic inhibition. These are the thyroid-stimulating hormone (TSH) and growth hormone (GH). The only pituitary

Figure 3 Summary of pituitary hormones and their main actions.

hormone that is primarily under hypothalamic inhibition is prolactin (PRL).¹⁰

Oxytocin

Oxytocin is a nonapeptide hormone produced in the paraventricular and supraoptic nuclei of the hypothalamus. The hormone is transported to nerve endings in the neurohypophysis and is secreted in response to stimuli originating in the uterus and mammary glands. The main functions of this hormone are promotion of breast-feeding and initiation of uterine contractions during labor. In the female mammary glands, oxytocin acts to initiate the “let-down” reflex, causing milk to be secreted into the subareolar sinuses and from there via the mammary ducts to the nipple.¹¹

Oxytocin also binds to specific oxytocin receptors in the uterus, causing both uterine contractions and cervical dilatation during the second and third phases of labor. Due to this action, many women experience uterine contractions during the first few weeks of lactation.

Oxytocin has an unclear role in the sexual response. The hormone plasma levels have been shown to rise during the human orgasm in men and women. Other data suggest that

this increase in plasma levels occurs throughout sexual arousal, not specifically during the human orgasm. Some women also describe sexual arousal during lactation.

The production of oxytocin is upregulated in situations concerning pregnancy, lactation, and menstrual cycles. It is produced from its precursor along with the neurophysin-1 protein, which serves as a carrier for the hormone itself. The hormone is carried to the posterior hypophysis at a slow rate, with a lag time between production and secretion of about half a day.¹²

Uterine contractions are enhanced by oxytocin secretion. This secretion, in turn, augments further contractions. Thus, the main feedback loop involved in oxytocin release is a positive feedback.

When suction is applied on the female nipple, and at times during sexual intercourse, the magnocellular neurons in the hypothalamus are stimulated, and a pulsatile release of oxytocin is started. The stimuli for this release are elaborate, and other, higher-function neurologic stimuli may also play a role in it, such as sexual excitation and anticipation and recollection of breast-feeding. The main stimulatory neurotransmitter involved in oxytocin secretion is acetylcholine.

Antidiuretic Hormone

ADH, also known as arginine-vasopressin, is a nanopeptide hormone synthesized in the supraoptic nucleus of the hypothalamus. As described for oxytocin, the hormone is transferred through axonal transport to the neurohypophysis, where secretion into the systemic circulation takes place.

The stimuli for secretion of this hormone are mediated by baroreceptors, mainly in the left atrium, aortic arch, and carotid sinus. These receptors are sensitive to changes in blood pressure. Further inputs are received from sensors of plasma osmolality throughout the body, but mainly in the supraoptic and paraventricular nuclei in the hypothalamus. A third stimulus is deficiency in glucocorticoid levels, whether central (originating from lowered ACTH or corticotropin-releasing hormone [CRH] levels; see later in this chapter) or peripheral (originating from adrenal hyposecretion, e.g., Addison disease). This elaborate sensory input facilitates both the antidiuretic and vasoconstricting actions of arginine-vasopressin.

The effects of ADH are due to binding of the hormone to specific target cell membrane-bound receptors. Its effect on the muscularis mucosa cells of arteries throughout the body is a strong vasoconstricting effect. Its effect on the distal renal tubular cells is an increase in the permeability of these tubules to water, thus increasing water reabsorption and concentration of urine. This, in turn, results in a larger effective circulating plasma volume.

Adenohypophysis

The adenohypophysis secretes six hormones: thyrotropin, or TSH; corticotropin, or ACTH; GH; the two gonadotropins, FSH and LH; and PRL. These hormones maintain homeostasis through their action on the hormone-secreting organs of the thyroid, adrenal cortex, and gonads and their various actions on bone, kidney, and breast.

Thyroid-Stimulating Hormone

Thyrotropin-releasing hormone (TRH) is synthesized in the hypothalamus and released into the portal system. It acts on thyrotroph cells in the anterior hypophysis, causing the release of TSH. TSH acts on follicle cells in the thyroid gland and stimulates them to secrete both triiodothyronine (T_3) and thyroxine (T_4). The effect of TSH on the follicle cells is through all stages of hormonal release, that is, upregulation of hormone production, upregulation of hormone maturation, and a stimulant effect on hormone release.¹³

Negative feedback is exerted through thyroid hormone receptors in both the hypothalamus and the anterior hypophysis, which inhibit TRH and TSH secretion, respectively. A second inhibiting effect on TSH release is through the action of somatostatin, a hormone released from the hypothalamus that inhibits TSH release. Thus, TSH secretion is under dual hypothalamic control, both an inhibitory and a stimulatory effect.¹⁴

Growth Hormone

GH, or somatotrophin, is a 191-amino acid polypeptide that maintains normal growth through elaborate mechanisms of action. Its main action is on bone, causing bone

growth, elongation, and synthesis of cartilage material. Its secondary action is that of a hyperglycemic agent, stipulated to bring about availability of building blocks for growth and development. It has glucose-secreting effects on muscle and adipose tissue. It has a glucose-elevating effect on the liver, both by induction of glycogenolysis and by stimulating gluconeogenesis.

The secretion of GH is pulsatile, with two daily peaks in plasma levels.

Growth hormone-releasing hormone (GHRH), or somatotrophin, is synthesized in the arcuate nucleus of the hypothalamus and secreted into the portal circulation. It binds to receptors on the somatotroph cells in the anterior hypophysis and stimulates the release of GH from these cells.

Different cells in the arcuate nucleus synthesize a second hormone, called somatostatin. This hormone is the main hormone exerting negative feedback on the production and release of GH. Somatostatin release is mediated by many feedback loops from the body, specifically the sensing of hyperglycemia in the blood circulation. The main induction of somatostatin secretion is by insulinlike growth factor-1 (IGF-1), secreted and released by the liver.¹⁵

Gonadotropins: LH and FSH

LH and FSH are glycoproteins secreted by the gonadotroph cells of the anterior hypophysis. Their action is through the release of sex hormones from the gonads—the ovaries in females and the testes in males. FSH binds to specific receptors on the granulosa cells in the ovary. Its main action is the stimulation of germ cell maturation. Specifically, this refers to initiation of the ovulatory cycle, induction of follicular maturation, and selection of the most suitable follicle for development and ovulation. In males, FSH stimulates testicular Sertoli cells to secrete inhibin, which has a paracrine stimulatory effect on spermatogenesis and sperm maturation. It also has feedback effects (see below) on the hypophysis and hypothalamus.

LH binds to specific gonadotropin receptors and stimulates ovulation in females and the production of testosterone in males. In females, it binds to receptors on the follicle and stimulates the production and release of estrogen, eventually leading to the LH surge and to ovulation. Moreover, LH stimulates the maturation of the remaining follicle to a corpus luteum and the hormonal support for the possible zygote implantation in the uterus during the luteal phase. In males, LH exerts its main action on Leydig cells, which release testosterone in response to LH stimulation. This hormone has a stimulatory effect on spermatogenesis and sperm maturation.

The main stimulus for gonadotropin secretion is by the stimulatory effect of the hypothalamic gonadotropin-releasing hormone (GnRH). This hormone is secreted in a circulatory manner, with rhythms of secretion every 90 minutes.¹⁵

Feedback loops operating on the release of gonadotropins are simpler in males than in females. In males, the main feedback loop is the negative feedback effect of sex hormones on the hypothalamic release of GnRH and the pituitary release of gonadotropins. Apart from the direct effect of sex hormones, the inhibin-FSH negative feedback

loop is also significant in males. As already mentioned, FSH stimulates inhibin secretion from the Sertoli cells in the testes. Inhibin inhibits both FSH biosynthesis and its secretion from the gonadotroph cells of the anterior hypophysis. Inhibin also inhibits GnRH secretion from the hypothalamus.

In females, a complex cycle of feedback loops results in an ovulatory cycle, which occurs every 28 days in the average, healthy, ovulating female. Several effectors, including sex hormones and exogenous and limbic system inputs, influence this cycle of hormonal balance. During the first 2 weeks of the menstrual cycle, the follicular phase takes place. In this phase, estrogen-based (mainly estradiol) sex hormones are dominant in creating negative feedback on the release of GnRH from the hypothalamus. At the end of this phase, concentrations of estradiol peak in the bloodstream. This has a reverse effect on the hypothalamic-hypophysis axis and brings about a surge in LH secretion, which correlates to the time of ovulation. In the second phase of the menstrual cycle, the hypophysis plays a minor role, and the diminished effect of hormonal regulation brings about a change in the balance of progesterone-estradiol secretion from the ovary, ultimately leading to the secretory phase of menstruation.

Adrenocorticotrophic Hormone

ACTH is synthesized by the corticotroph cells in the anterior hypophysis. The stimulus for this secretion is dual. The first stimulant for ACTH secretion is CRH. This 41-amino acid peptide is released mainly from the parvocellular layer in the paraventricular nucleus of the hypothalamus. The stimulus for release of CRH is complex, involving several neurotransmitter molecules. It is released in response to acetylcholine and serotonin, and its secretion is inhibited by noradrenaline and γ -aminobutyric acid (GABA). A second stimulant for ACTH release is by vasopressin secreted by the hypothalamus into the portal system.

The effect of ACTH is mainly on the middle layer of the adrenal cortex. It promotes the release of cortisol from the cells in the zona fasciculata of the adrenal cortex. ACTH has other actions on the adrenal cortex. It binds to specific ACTH receptors and stimulates both biosynthesis and secretion of most hormones from the adrenal cortex: glucocorticoids, mineralocorticoids, and androgenic steroids. However, as described elsewhere, secretion of hormones other than glucocorticoids is regulated by other higher-order inputs, such as the renin-angiotensin system and the gonadotropin-gonad axis.

Negative feedback is exerted by plasma cortisol levels on both levels of the axis. Both CRH and ACTH production and secretion are inhibited by specific cortisol receptors, in both the hypothalamus and the anterior hypophysis.¹⁶

The secretion of ACTH, as well as that of cortisol, has a diurnal variation. It is influenced by sleep cycles and by light-dark external influence. It has been stipulated that one of the most significant contributions to this diurnal secretion is brought about by the effect of the suprachiasmatic nucleus.¹⁷

Of note, ACTH bears molecular and structural resemblance to the melanocyte-stimulating hormone, which stimulates melanin production. The two molecules share the same precursor protein, and their similar structure is significant in clinical practice.¹⁸

Prolactin

PRL is a peptide hormone secreted by the anterior hypophysis. The main hypothalamic effect on pituitary PRL release is inhibitory. This inhibition is exerted mainly by dopamine secretion into the portal system by the arcuate nucleus of the hypothalamus. The main hypothalamic secretory effect on prolactin is that of TRH.

PRL stimulates lactation in the mammary glands. It affects both the production of milk in the adenomatous parts of the female breasts and the myoepithelial expulsion of milk from the breast. During pregnancy, there is a delicate balance between the action of PRL and the action of progesterone. Increased levels of PRL stimulate the mammary glands to enlarge and prepare for the production of milk. Increased levels of progesterone, on the other hand, inhibit actual milk production. After birth, a fall in plasma progesterone levels causes unopposed prolactin action, which causes production of milk for the initiation of lactation.

PRL also has an inhibitory effect on the gonadal secretion of sex hormones—estrogen in females and testosterone in males. The pituitary hormone has also been shown to play a role in human sexual gratification and the sexual refractory period, both experienced after completion of the sexual act. Again, there is a delicate balance between the effect of PRL and the effect of another hormone—dopamine, in this instance. Dopamine is responsible for sexual arousal and is counteracted by the action of PRL. To simplify this balance, during sexual arousal and the sexual act, dopamine-related sensations predominate. After (and possibly during) an orgasm, the action of PRL predominates, and sexual gratification and the refractory period ensue. This delicate balance also plays a role in several pathologic scenarios, including elevated PRL levels and the resultant sexual dysfunction, the treatment of PRL-secreting macroadenomas with dopamine agonists, and the galactorrhea associated with dopamine antagonism in the treatment of psychosis.¹⁹

Secretion of PRL is a diurnal one. Other factors that influence the levels of PRL in the serum include the stage in the female ovulatory cycle, pregnancy status, and postpartum newborn breast-feeding activity. Sucking on the nipple affects the hypothalamic modulation of PRL secretion, thereby increasing PRL secretion by the adenohypophysis. Therefore, the newborn maintains a positive feedback loop with the mother's hypophysis and a negative feedback loop with the mother's hypothalamus. This positive feedback brings about an increase in milk production and maternal adaptation to the child's increasing metabolic needs.

CONCLUSION

The pituitary gland is the main point where the neural and endocrine systems function in continuity, maintaining homeostasis of many functional elements of the human body. Among these are thermoregulation; metabolism and metabolic rate; glucose and solute, as well as water balance; growth and development; blood pressure; and sexual drive, pregnancy, childbearing, birth, and breast-feeding. The devastating effects of pituitary dysfunction underscore the importance of the pituitary gland in maintenance of the various functions that underlie normal, everyday human activity. The complex interactions—between the nervous

system and the hormonal system, between the hypophysis and the hypothalamus, and between the hypophysis and the hormone-secreting organs it modulates—are a reflection of the narrow window of variability our body must maintain.

Adrenal Glands

Failure of adrenal function will result in disordered electrolytes and carbohydrate metabolism, which may lead to circulatory collapse, hypoglycemic coma, and death. The adrenal cortex produces a complex array of steroid hormones, whereas the medulla is part of the sympathetic nervous system and produces the catecholamines epinephrine and norepinephrine. The cortex and medulla of the adrenal glands differ embryologically and physiologically, but their hormones often act in a concerted manner.

EMBRYOLOGY AND DEVELOPMENT

The human adrenal glands are bilateral structures sitting above the kidneys and consist of an outer cortex and an inner medulla, both of which secrete hormones that are essential for life. The medulla accounts for about 10% of the mass of the adult adrenal gland and arises from the neuroectoderm; it is thus a modified sympathetic ganglion. By contrast, the cortex arises from mesodermal tissue.²⁰

The cells of the adrenal cortex originate from the intermediate mesoderm and are initially part of the adrenogonadal primordium within the urogenital ridge.^{21,22} They may be detected as early as human embryonic week 4¹⁶ and separate as a distinct adrenocortical primordium from the gonadal primordium by week 8.²³ This adrenocortical anlage consists of two layers: the outer definitive zone and the inner fetal zone. However, whether the cells of these two layers share a common precursor remains a conundrum.²⁴ By week 9 of gestation, neural crest cells migrate into the adrenal anlage to form the medulla, and the newly formed organ becomes encapsulated. At this time, the fetal adrenals are huge in proportion to other organs and continue to grow until the third trimester. The cortex's definitive zone appears steroidogenically quiescent until late gestation, and the inner fetal zone appears steroidogenically active throughout gestation. An additional transitional zone appears after 24 weeks' gestation and produces cortisol toward the end of the fetal development.^{23,25} At birth, the fetal adrenals weigh 8 to 9 g, twice the weight of the adult adrenals.

After birth, the large fetal zone of the fetal adrenal involutes and disappears by 6 months of age. Simultaneously, the definitive zone, possibly together with the transitional zone, develops into the fully differentiated zona glomerulosa and zona fasciculata by the age of 3 years. However, the zona reticularis starts to develop only after 4 years of age and may not be fully differentiated before the age of 15 years [see Figure 4]. The origin and regulation underlying the zonation of the human adrenal gland are still poorly understood.^{23,25,26}

ANATOMY

The adrenal (suprarenal) glands are located between the superomedial aspects of the kidney and the diaphragm. Each adrenal gland, together with the kidney, is enclosed in the renal fascia (of Gerota) and surrounded by fat. The

glands are separated from the kidney by a fibrous tissue but are enclosed by renal fascia, which firmly attaches them to the diaphragm.^{27,28}

Each adrenal gland has only anterior and posterior surfaces. The shape and anatomic relations of the adrenals differ on the two sides:

- The right adrenal is triangular in shape.
 - The anterior surface is bounded by the “bare area” of the liver superiorly and laterally, the inferior vena cava (IVC) medially, and the first part of the duodenum or peritoneum inferiorly.
 - The posterior surface is bounded by the diaphragm superiorly and the kidney inferiorly.
- The left adrenal gland is semilunar in shape. The anterior surface is bounded superiorly by the peritoneum (posterior wall of the omental bursa) and inferiorly by the body of the pancreas. The posterior surface is bounded medially by the left diaphragmatic crus and laterally by the medial aspect of the left kidney. The spleen is located anterolaterally and superiorly to the adrenal gland.

The adrenal glands are located 4 to 5 cm apart, and between the glands from right to left are the IVC, right crus of the diaphragm, celiac ganglion, celiac trunk, superior mesenteric artery (SMA), celiac ganglion, and left crus of the diaphragm.

Vessels of the Adrenal Glands

The endocrine function of the adrenal glands makes their abundant blood supply necessary [see Figure 5]. The adrenal arteries branch freely before entering each gland, so 50 to 60 arteries penetrate the capsule covering the entire surface of the glands.

Arterial Blood Supply

Six to eight superior adrenal (suprarenal) arteries branch from the inferior phrenic artery that is the first abdominal branch of the aorta. The middle adrenal (suprarenal) arteries (one or more) branches form the abdominal aorta just proximal to the origin of the renal arteries. They can be single, multiple, or absent and supply the perirenal fat only. Inferior adrenal (suprarenal) arteries (one or more) arise from the renal artery usually proximal to the bifurcation of the renal segmental arteries.

Venous Drainage

Venous drainage of the adrenal gland does not accompany the arterial supply. Venous drainage is into a large adrenal (suprarenal) vein.

On the right, the short right adrenal vein passes obliquely and drains directly to the IVC posteriorly. In contrast, the left adrenal vein passes downward over the anterior surface of the left adrenal gland. It is often joined by the left inferior phrenic vein and empties into the left renal vein.

Occasionally, an adrenal gland has two veins, one following a normal course and the other being an accessory vein that drains into the inferior phrenic vein.

Lymphatic Drainage

The adrenal lymphatic vessels arise from a plexus deep to the capsule of the gland and from one in the medulla. The

Figure 4 The adrenal layers and hormones.

subcapsular plexus follows the arteries, and the medullary plexus follows the adrenal veins. Drainage is to renal hilar nodes, lateral aortic nodes, and nodes of the posterior mediastinum above the diaphragm by way of the diaphragmatic orifices for the splanchnic nerves. The lymph passes to the lumbar lymph nodes. The lumbar nodes drain through the lumbar lymphatic trunks to the chyle cistern. However, the majority of capsular lymphatic vessels pass directly to the thoracic duct without the intervention of lymph nodes.

Lymphatic vessels of the upper pole of the right adrenal gland may directly enter the liver.

Nerves

The adrenal glands have a rich nerve supply from the celiac plexus and the thoracic (greater, lesser, and least) splanchnic nerves. Some of the abdominopelvic splanchnic nerves convey presynaptic sympathetic fibers that have passed through the paravertebral ganglia without synapsing

Figure 5 The adrenal blood supply and venous drainage.

to the prevertebral ganglia. The nerves are mainly myelinated presynaptic sympathetic fibers that derive from the lateral horn of the spinal cord and distributed to the chromaffin cells in the adrenal medulla. Exclusively in the case of the adrenal medulla, the presynaptic fibers also pass the vertebral ganglia without synapsing, to end directly on the secretory cells of the adrenal medulla.

NORMAL PHYSIOLOGY

Each adrenal gland is composed of two endocrine organs, one surrounding the other. The outer layers composing the adrenal cortex secrete glucocorticoids, aldosterone, and sex hormones. The inner layers compose the adrenal medulla and secrete catecholamines [see Figure 4]. This part of the chapter separately reviews the synthesis, action, and regulation of each hormone.

Glucocorticoids

Thomas Addison discovered in the mid-1800s that the adrenal cortex is essential for survival.²⁹ During the following century, many of the actions of glucocorticoids were characterized. Glucocorticoids were named for their hyperglycemic effect. In the mid-20th century, this effect was further clarified. In 1940, Long and colleagues demonstrated that glucocorticoids stimulate gluconeogenesis from amino acids and elicit steroid diabetes.³⁰ At the same time, steroids' role in stress and feedback regulation was established. The antiinflammatory effect of glucocorticoids was a matter of debate until two decades later.

Synthesis Synthesis of glucocorticoids is almost exclusively limited to the adrenal cortex, where it is closely tied to ACTH. ACTH is secreted by the hypophysis and exhibits circadian rhythm similar to glucocorticoid's plasma levels. ACTH stimulates steroidogenesis by binding to membrane receptors on adrenal cells, which activate adenylate cyclase and cause hypertrophy and hyperplasia of the adrenal cortex.³¹

Cholesterol is the substrate for the synthesis of all steroid hormones. Figure 6 demonstrates the synthesis sequence

of the different hormones. Both low-density lipoproteins (LDLs) and high-density-lipoproteins (HDLs) are used as substrates by cytochrome P-450 enzymes to synthesize cortisol. The rate-limiting process in steroidogenesis is the transport of free cholesterol through the cytosol to the inner mitochondrial membrane. Within the mitochondria, pregnenolone is derived from cholesterol and is then converted to progesterone. Progesterone is then converted to 17 α -hydroxypregesterone, which in turn is hydroxylated to 11-deoxycortisol, which is finally hydroxylated to cortisol.^{32,33}

Actions Glucocorticoids play an important role in carbohydrate, protein, and fat metabolism. Moreover, glucocorticoids have multiple effects on many different end-organs, and some of these effects are not yet fully understood:

1. Glucocorticoids raise blood glucose level. They protect the body from insulin-induced hypoglycemia. This is achieved by mobilizing gluconeogenic substrates from peripheral tissues, stimulating hepatic gluconeogenesis, enhancing the effect of glucagon and epinephrine on gluconeogenesis and glycogenolysis, inhibiting peripheral glucose use, stimulating lipolysis, and promoting liver glycogen synthesis. Glucocorticoids' actions interact with those of insulin during feeding and fasting, influencing appetite, feeding patterns, and body composition. Chronic high levels of glucocorticoids lead to massive catabolic effects on proteins, resulting in muscle wasting and lipolysis and redistribution of fat.³⁴
2. Glucocorticoids act on bone and cause osteoporosis by inhibiting the function of osteoblasts and collagen synthesis.³⁵
3. Glucocorticoids suppress the inflammatory and immune response. Blood counts of lymphocytes, monocytes, eosinophils, and basophils drop within 1 to 3 hours of glucocorticoid administration. Glucocorticoids protect against overactivity of immune reactions by suppressing proinflammatory cytokines and histamine and enhancing the production of antiinflammatory cytokines.³⁶
4. Glucocorticoids have complex effects on the cardiovascular system. Glucocorticoids enhance vascular reactivity to

Figure 6 Synthetic pathways for adrenal steroid synthesis. DHEA = dehydroepiandrosterone; DHEAS = dehydroepiandrosterone sulfate.

other vasoactive agents (angiotensin II, norepinephrine) and contribute to maintaining normal blood pressure. In contrast, chronic exposure to high levels of glucocorticoids frequently leads to hypertension.³⁷

5. Glucocorticoids directly increase Na^+ and K^+ secretion in the kidney and in the colon. Phosphaturia and diuresis are also induced.
6. Glucocorticoids influence behavior, mood, excitability, and electrical activity of neurons. Behavioral changes are frequently observed with both excess and deficit of glucocorticoids.³⁸

Regulation and feedback Cortisol secretion by the adrenal cortex is regulated by a negative feedback system involving the hypothalamus and anterior pituitary. As mentioned earlier, ACTH from the anterior pituitary stimulates the adrenal cortex to secrete cortisol. Cortisol inhibits the secretion of both CRH and ACTH by the hypothalamus and anterior pituitary, respectively.

It is now known that cytokines also play a role in the complex feedback. Cytokines communicate between the immune system and the hypothalamic-pituitary-adrenal axis. Interleukin-1 (IL-1), $\text{IL-1}\alpha$, $\text{IL-1}\beta$, IL-6 , and tumor necrosis factor- α increase levels of glucocorticoids, ACTH, and CRH.^{39,40}

Aldosterone

The steroid hormone aldosterone, synthesized in the zona glomerulosa of the adrenal cortex, plays a pivotal role in electrolyte and fluid balance. Aldosterone was first isolated in 1953 with the use of the toad urinary bladder as a model system.⁴¹

Synthesis The first synthesis steps of aldosterone resemble those of glucocorticoid. Progesterone is also the substrate for mineralocorticoid synthesis. In the zona glomerulosa, progesterone is hydroxylated to yield deoxycorticosterone. All three terminal steps in the conversion of this intermediate to aldosterone are catalyzed by a single mitochondrial P-450 enzyme, aldosterone synthase.³² The zona glomerulosa is well adapted for the production of aldosterone. It has a low concentration of 17-hydroxylase, the enzyme that directs substrate along the pathways to cortisol and androgen synthesis, and is the only adrenocortical zone that has the enzyme required for the sequential conversion of deoxycorticosterone to aldosterone.⁴² The restriction aldosterone synthase expression to the zona glomerulosa allows aldosterone production that is not effected by ACTH.

Action As the term mineralocorticoid implies, the classic effects of aldosterone reflect its role in the regulation of electrolyte flux across transporting epithelia. Aldosterone increases transepithelial sodium flux in the distal nephron and the distal colon.⁴² Aldosterone acts on the cells via the mineralocorticoid receptor to induce gene transcription of sodium channels. Water ultimately follows the movement of Na^+ via osmosis, establishing chronically increased blood volume and thus blood pressure.

Aldosterone acts on epithelial cells of the renal collecting duct and regulates sodium transport. The transcellular transport across these cells is electrogenic and dependent on

serosal Na^+/K^+ -ATPases and luminal amiloride-sensitive epithelial Na^+ channel (ENaC) and K^+ channels. Aldosterone increases the activity of both the serosal pump and luminal channels in the kidney and the colon.⁴³

Aldosterone has been shown to induce cardiac fibrosis in the hypertensive or failing heart and to alter cardiac remodeling after myocardial infarction.⁴⁴ Aldosterone also mediates substantial changes in blood pressure via CNS-regulated functions, including control of sodium intake.⁴⁵

The net effect of aldosterone is sodium resorption, volume expansion, hypertension, suppression of renin activity, hypokalemia, and metabolic alkalosis.

Regulation and feedback The most important feedback loop involves the renin-angiotensin system. Volume status is sensed by the renin-secreting juxtaglomerular cells of the kidney. When the volume (and sodium) is low, renin will be secreted. Renin release is stimulated by renal perfusion pressure, the sympathetic nervous system, and prostaglandins. The release is inhibited by dopamine, atrial natriuretic peptide (ANP), and angiotensin II. Renin acts on angiotensinogen to release angiotensin I, which in turn is subject to further proteolysis by angiotensin-converting enzyme to yield angiotensin II. Angiotensin II acts as a potent vasoconstrictor and stimulates aldosterone synthesis. The latter response promotes sodium retention and consequently increases plasma volume.⁴²

The secretion of aldosterone is also stimulated by potassium, so a negative feedback loop exists for potassium and aldosterone. Other stimulators include ACTH, vasopressin, and serotonin. Negative feedback on aldosterone secretion is carried out by somatostatin; ANP, which promotes natriuresis; and dopamine, which is a well-characterized inhibitor.⁴⁶

Adrenal Sex Hormones

The main site of sex hormone production is the gonads—the testes for androgens in males and the ovaries for estrogens in females. Accordingly, males have a preponderance of circulating androgens, whereas in females, estrogens predominate. However, no hormones are unique to either males or females because the adrenal cortex in both sexes produces small amounts of the sex hormone of the opposite sex. Adrenal sex hormones are synthesized in the zona reticularis and are identical to those produced by the gonads. The most abundant of the adrenocortical sex hormones is dehydroepiandrosterone (DHEA), a “male” sex hormone.⁴⁷

Synthesis Adrenocortical sex hormones are formed in the zona reticularis, which has no type 2,3 β -hydroxysteroid dehydrogenase.^{32,47} Therefore, 17-hydroxypregnenolone can be directed to DHEA. Androstenedione, another weak androgen, is produced by side-chain cleavage of 17 α -hydroxyprogesterone by P-450c17 and is subsequently converted to testosterone by 17-ketosteroid reductase, mainly in peripheral tissues. Because the enzymes required for the production of estrogens are found in very low concentrations in adrenocortical cells, the normal level of adrenal estrogen production is very low. There is also minimal synthesis of testosterone in the adrenal gland [see Figure 6].

Action Under normal circumstances, the adrenal androgens and estrogens are not produced in such levels to induce masculinizing or feminizing effect, respectively. Of all the adrenal sex hormones, only the androgen DHEA is of any physiologic importance. In males, DHEA has little effect as it is much weaker than the potent testosterone; nevertheless, in females who otherwise lack androgen, DHEA has a more significant effect. This androgen is responsible for androgen-dependent processes in the female such as the growth of pubic and axillary hair, enhancement of the pubertal growth spurt, and development and maintenance of the female sex drive.⁴⁸

Other than inducing the above processes in females, it is postulated that DHEA plays a role in aging. A surge of DHEA begins at puberty and peaks between ages 25 and 30. After age 30, DHEA levels slowly decrease, so by the age of 60, the levels are less than 15% of its peak. Supplementation with DHEA has been claimed to have antiaging effects, including increased libido, enhanced immune function, increased muscle mass, and improvements in energy, mood, and memory.^{49,50} The risks of DHEA supplements include reduction in HDL levels, increased facial hair in women, and possible increased risk of ovarian, breast, and prostate cancer.^{51–53}

Several extra-adrenal factors have been proposed as stimuli of adrenal androgen secretion. These factors include PRL, for which there are abundant receptors on adrenocortical cells. In women with prolactinomas, serum DHEA sulfate concentrations are weakly correlated with serum PRL concentrations.⁵⁴

Regulation and feedback Surprisingly, adrenal androgen production is controlled by ACTH and not by pituitary gonadotropic hormones. However, DHEA does inhibit the hypothalamic secretion of GnRH in the same manner as testicular androgens do.

PRL induces adrenal androgen secretion through the abundant PRL receptors present on adrenocortical cells.⁵⁴ Adrenal androgen secretion is also affected by lymphocytes. Lymphocytes increase DHEA secretion by adrenal cells fourfold in vitro, an effect greater than that of maximally stimulating ACTH concentrations. In contrast, androgen secretion is reduced in patients receiving T lymphocyte-suppressive drugs.⁵⁵

Catecholamines

The adrenal medulla is part of the sympathetic nervous system and consists of modified postganglionic neurons that secrete their transmitters directly into the circulation. The adrenal medulla synthesizes mainly epinephrine (80%) and, to a lesser degree, norepinephrine (20%); both belong to the chemical class of catecholamines and differ only by a methyl group that is present in the former. Although adrenomedullary hormones are not essential for life, virtually all organs in the body are affected by these catecholamines.⁵⁶

Synthesis Catecholamine synthesis begins with the amino acid tyrosine. Tyrosine hydroxylase converts L-tyrosine to dopa [see Figure 7]; therefore, tissue sources for catecholamines depend on the presence of the enzyme that is confined to dopaminergic and noradrenergic neurons of the

CNS and to sympathetic nerves and chromaffin cells of the adrenal medulla.⁵⁷ Dopa is decarboxylated to dopamine that is stored in granules. Dopamine is converted to norepinephrine by dopamine β -hydroxylase in the vesicles. In adrenal medullary chromaffin cells, norepinephrine is metabolized to form epinephrine, which is translocated into granules and awaits release.⁵⁸ The process of exocytosis is controlled primarily by acetylcholine release from innervating splanchnic cells.

Action As mentioned above, medullary catecholamines affect almost all body organs; to review all the effects is beyond the scope of this chapter. A simple way to understand the action of catecholamines is to consider them as hormones of the “fight or flight” response. The effects are mediated by two major subtypes of adrenergic receptors: alpha and beta receptors. The alpha-adrenergic receptors bind both catecholamines. The beta-adrenergic receptors, especially the β_2 receptor, are primarily receptors for epinephrine. This difference in affinity results in divergent effects⁵⁹:

- Heart: increased force and contractility (β_1)
- Blood vessels: peripheral vasoconstriction ($\alpha_1 > \alpha_2$), vasodilation (β_2)
- Kidney: increased renin release (β)
- Gastrointestinal: decreased motility and increased sphincter tone (α and β)
- Pancreas: decreased insulin (α) and increased glucagon (β)
- Liver: increased glucose and glucagon (α and β)
- Adipose: increased lipolysis (β_3)
- Skin: increased sweating (α)
- Bronchiole: dilation (β_2)
- Uterus: constriction (α) and relaxation (β_2)
- Most tissues: increased heat (β , along with thyroid hormone)

The combined effects of norepinephrine and epinephrine are to increase cardiac output, heart rate, blood pressure, and respiration (epinephrine is a powerful bronchodilator). They also increase blood flow to the muscles while decreasing splanchnic and renal blood flow. Finally, they increase alertness (chronic stimulation results in anxiety). The net effects are to reroute blood to the muscles and to prepare the brain to control the anticipated physical activity.

Epinephrine (and, to some extent, norepinephrine) has effects in all of the major tissues involved in energy metabolism. In the liver, these hormones stimulate glycogen and lipid breakdown. Epinephrine also stimulates gluconeogenesis and glucose release into circulation. The combination of the effects is a large increase in glucose availability, which can lead to hyperglycemia in cases of prolonged stimulation.

In skeletal muscle, epinephrine also stimulates glycogen breakdown. However, in muscle, epinephrine slightly stimulates glycolysis. The effect of epinephrine in muscle is a preparation for the demands of exercise. To further glucose availability, epinephrine stimulates lipolysis in adipose tissues, and both epinephrine and norepinephrine decrease pancreatic production of insulin and increase glucagon secretion.

Figure 7 Major steps in catecholamine synthesis and degradation.

Regulation and feedback In the adrenal medulla, epinephrine and norepinephrine are stored in chromaffin granules with other compounds. Activation of the sympathetic nervous system is coordinated by the medulla oblongata and results in acetylcholine secretion. In turn, acetylcholine causes depolarization of the chromaffin cells, influx of calcium, and exocytosis of the granules. The release signal is triggered by stressors, such as anxiety, fear, pain, trauma, hemorrhage or other fluid loss, changes in pH of the blood, increased energy demand (especially for exercise), hypoglycemia, or exposure to excessive heat or cold. Most, if not all, of the granule contents play some role in preparing the body to respond to these types of stress.⁶⁰

The two enzymes that are involved in catecholamine inactivation are catechol-*O*-methyl transferase (COMT) and monoamine oxidase (MAO). Most of the metabolism of the catecholamines occurs in the liver, which contains COMT and MAO and a number of other enzymes. The two major metabolites produced by these enzymes are metanephrines (15%) and vanillylmandelic acid (VMA) (85%), which are secreted through urine⁶¹ [see Figure 7].

CONCLUSION

The adrenal glands constitute two different hormone-secreting organs: the cortex and the medulla. Whereas the cortex secretes steroids, the medulla produces catecholamines and as such is considered part of the sympathetic nervous system. Despite the differences in hormone secretion, both adrenal parts are vital for life. The adrenal anatomy differs between the left and right sides, and meticulous knowledge of the variations may prevent devastating complications when performing surgery. Every surgeon who attempts to manage patients with adrenal diseases must be familiar with the detailed physiology of hormone synthesis, feedback, and degradation. Such knowledge will enable proper understanding of both the preoperative evaluation and the correct intra- and postoperative management of these potentially complicated patients.

9 ANATOMY AND PHYSIOLOGY OF THE PANCREAS

John A. Windsor, MBChB, MD, FRACS, FACS

The casual observer might be forgiven for assuming that the pancreas played an insignificant role given its size, morphology, and location. Indeed, Galen and anatomists for a millennium considered the pancreas a fatty cushion on which the stomach rested. Even the 1901 edition of *Gray's Anatomy* stated that the “pancreas presents but little of surgical importance.”¹ In truth, this largest digestive gland, situated in the center of the body, on either side of the transpyloric (L1) plane, is notable for its complex anatomy and the colocation of exocrine and endocrine organs. The pancreas is an organ of endless fascination, with the congenital anomalies giving rise to a range of anatomic variations; the anatomic relations challenging the most meticulous of surgeons; and the wide-ranging pathology of clinical significance.

Surgery of the pancreas requires a detailed understanding of the anatomy of the pancreas and its relation to adjacent vital structures, and the management of patients with diseases related to the pancreas requires a detailed understanding of the physiology of both the exocrine and the endocrine pancreas. The functional reserve of the gland is such that over 50% of its acinar tissue must be destroyed before there is marked evidence of an effect on digestion.

Morphology of the Pancreas

The pancreas, weighing about 80 g, is shaped like a tadpole, with a thicker head and a flatter neck, body, and tail [see Figure 1]. It is salmon pink with a smooth, lobulated surface. Fixed within the retroperitoneum, the pancreas is draped obliquely over the spinal column and major vessels,

with the head hugged by the duodenum and rising to where the tail touches the splenic hilum in the left upper quadrant. This obliquity accounts for why cross-sectional imaging does not display the entire pancreas on a single slice [see Figure 2]. Being within the retroperitoneum means that inflammatory extravasation of the pancreas can readily spread in many directions, including the anterior and posterior pararenal spaces, paracolic gutters, small bowel mesentery, transverse mesocolon, and even the mediastinum and scrotum [see Figure 3]. With severe acute pancreatitis, the extravasations can pass from the anterior to posterior pararenal spaces and are seen as subcutaneous discoloration in the flanks (Grey-Turner sign). If the extravasation tracks in the falciform ligament, the discoloration can present at the umbilicus (Cullen sign).

Lying as it does, the pancreas has intimate relations with more anatomic structures than any other organ in the body, including the duodenum, common bile duct (CBD), stomach, transverse colon, left kidney, left adrenal, and spleen [see Figure 4]. There are also vascular relations to the inferior vena cava and left renal vein, the aorta and its branches (celiac trunk and branches, superior mesenteric artery [SMA]), and portal, superior mesenteric, and splenic veins. The proximity of the pancreas to these structures makes them prone to invasion by malignant pancreatic disease. The pancreatic head bounded by the duodenum (above, below, and to the left) has an important relation with the CBD. As the duct descends behind the first part of the duodenum, it becomes enclosed by ($\approx 80\%$) or grooves ($\approx 20\%$) the pancreas as it passes to exit at the major duodenal papilla.*

Figure 1 General morphology of the pancreas.

Financial disclosure information is located at the end of this chapter before the references.

* “Papilla” refers to the nipple appearance and projection of the duodenal mucosa through which the ampulla exits. The ampulla is increased caliber of the conjoined main pancreatic duct and the CBD, and is absent if these ducts exit separately.

Figure 2 Computed tomography scans of normal pancreas. (a) Pancreatic body and tail. (b) Pancreatic neck. (c) Pancreatic head and uncinate process (demonstrating plane surrounding superior mesenteric artery and the inferior pancreaticoduodenal artery).

This close relation to the CBD is the reason why jaundice, by malignant encroachment of the duct, is often the first presenting sign of pancreatic head adenocarcinoma. For many years, the decision that a cancer of the pancreatic head was unresectable has been based on demonstration of invasion of the portal and superior mesenteric veins. However, in major centers today, the invasion of the SMA and, less commonly, the celiac and common hepatic arteries has become a more important determinant of unresectability. This is because en bloc venous resection can be performed safely and can be justified when all other resection margins are negative.

To display the anterior surface of the pancreas requires the gastrocolic omentum to be widely opened and division of the inevitable and variable congenital adhesions between the pancreatic peritoneum and the overlying lesser curve of the stomach. The transverse mesocolon arises away from the pancreas except where it crosses the second part of the duodenum and uncinate process of the pancreas. This means that the lower border of the uncinate process can be palpated and is often seen from the greater omental sac through the root of the transverse mesocolon. Full exposure of the anterior head of the pancreas (and the second and third

parts of the duodenum) requires this attachment of the transverse mesocolon to be divided. Complete exposure of the neck of the pancreas requires division of the gastrocolic trunk, and associated lymphatic nodes (see below), which crosses it. This trunk contains the gastroepiploic artery (from the SMA), the gastroepiploic vein (which drains into the superior mesenteric vein [SMV]), and lymph nodes. The trunk is also joined by the gastroduodenal artery (GDA; from the common hepatic artery) after it has descended on the pancreatic neck. Division of the lesser (gastrohepatic) omentum and caudal retraction of the gastric antrum and pylorus is another way to expose the anterior neck of the pancreas. Other aspects of the pancreas can also be accessed through different routes. The Kocher maneuver frees the horizontal and retroperitoneal second part of the duodenum to expose the posterior pancreatic head. The transverse mesocolon can be opened to the left from the greater omental sac to expose the inferior margin of the pancreatic body. The splenic flexure can be mobilized to expose the lower pole of the spleen, hilum, and pancreatic tail.

The head of the pancreas is the broadest part of the gland. The superior aspect of the head is derived from the dorsal anlage of the gut tube. The uncinate process of the pancreas

Figure 3 Pathways of pancreatic extravasations. BL = bladder; C = colon; D = duodenum; LV = liver; P = pancreas; R = rectum; SI = small intestine; ST = stomach.

is derived from the ventral anlage, which, through a process of rotation and fusion within the first month, forms the inferior portion of the pancreatic head.² It is highly variable in shape and occasionally absent, but it is called the uncinate process because it is considered hooklike, usually passing downward, to the left, and behind the superior mesenteric vessels but in front of the vena cava and aorta [see Figure 5]. The medial border of the uncinate process is the SMA, and this margin is the one most often positive with resection of the pancreatic head for adenocarcinoma. Special attention must be given to this margin by the radiologist when staging a cancer by cross-sectional imaging [see Figure 2c]

and by the surgeon by dissection on the SMA to minimize the chance of incomplete clearance. Branches of the SMA (the inferior pancreaticoduodenal artery [IPDA]) and tributaries of the SMV enter the medial aspect of the uncinate process.

The neck of the pancreas is defined as that portion of the gland that crosses the superior mesenteric vessels and is usually less than 2 cm wide [see Figure 4]. Anteriorly, it is partially covered by the pylorus, and posteriorly, the portal vein is formed by the confluence of the superior mesenteric and splenic veins. The inferior mesenteric vein terminates in the splenic vein in over a third of patients but can also

Figure 4 The relationship of the pancreas to other organs.

terminate in the SMV or at the confluence of the two. Establishing that there is no invasion of these subjacent veins is an important part of the staging and dissection of a pancreatic cancer of the head and neck. To that end, it is common practice to establish a plane between the neck and these veins, facilitated by the absence of an anterior tributary draining from the pancreas at this point. The celiac trunk and its trifurcation arise at the superior margin of the neck, and the superior mesenteric vessels leave the inferior margin to cross the third part of the duodenum and enter the mesentery of the small bowel.

The body of the pancreas lies along the floor of the lesser sac (or omental bursa) and is covered by peritoneum derived from the superior leaf of the transverse mesocolon. Posteriorly, the body of the pancreas is related to (from right to left) the aorta, the origin of the SMA that arises just above the left renal vein, the left crural pillar of the diaphragm, and the left kidney and its vessels. The splenic vein coursing posteriorly to the spleen has a variable relation with the pancreas. Receiving multiple small tributaries from the pancreas, the splenic vein may be separate from or covered

Figure 5 The uncinate process, which can vary in medial extent to the SMV (a), under the SMV (b), or behind the SMA (c).

by the gland. The splenic artery can be seen looping above the superior margin of the pancreas.

The tail of the pancreas is the most mobile part of the pancreas and has a variable relation with the spleen. The tail of the pancreas extends to the spleen (and occasionally onto the spleen) and can do so anterior to, posterior to, or within the splenic hilum. This relation should be defined at the time of splenectomy to avoid injury to the pancreatic tail. Also entering the splenic hilum are the short gastric vessels and the left gastroepiploic vein. Understanding the peritoneal reflections of the splenic hilum is important for accurate dissection of this area [see Figure 6].

Ductal System of the Pancreas

Secretions from the 20 to 200 acinar cells within each pancreatic lobule drain into small intercalated ducts. These merge to form intralobular ducts, which further merge to form secondary pancreatic ducts that drain at right angles into the main pancreatic duct (MPD or duct of Wirsung) [see Figure 7]. The MPD runs from the distal pancreatic tail to the head of the pancreas, gradually increasing in caliber from approximately 1 to 2 mm in the tail, 2 to 3 mm in the body, and 3 to 4 mm in the head. The entire volume of the pancreatic ductal system is usually less than 3 mL, and the injection of contrast into the duct should be low pressure and low volume at the time of endoscopic retrograde cholangiopancreatography (ERCP) to reduce the risk of procedure-related acute pancreatitis. Through the body and tail, the MPD usually lies slightly more superior and posterior

than the cross-sectional midpoint of the gland. It is common for the MPD to become more posterior and caudad as it passes from the neck into the head. The uncinete process has its own pancreatic duct, which usually drains into the MPD as it becomes more horizontal, just short of the major duodenal papilla. There is, however, significant variation in the arrangement of these ducts [see Figure 8].

The accessory pancreatic duct (of Santorini) is the proximal portion of the duct draining the dorsal pancreas. With fusion of the ducts from the dorsal and ventral pancreas, the accessory duct assumes a secondary role and tends only to drain the anterosuperior portion of the pancreatic head. However, when the ducts do not fuse ($\approx 10\%$), called pancreas divisum, the accessory duct drains the entire dorsal pancreas and none of the uncinete process. The minor duodenal papilla, located approximately 1 to 2 cm proximal and anterior to the major duodenal papilla, may be responsible for pancreatitis because the small-caliber duct causes a relative obstruction at the time of stimulated pancreatic secretion, although this contention is somewhat controversial. The minor duodenal papilla is absent in up to a third of the population. An anomalous junction between the MPD and the CBD has been described³ and is associated with fusiform dilatation of the CBD, the most common type of choledochal cyst. Whether this abnormal junction is a cause of recurrent pancreatitis is still disputed.

Major Duodenal Papilla

The major duodenal papilla is located on the posteromedial wall of the duodenum, in the second part, 7 to 10 cm distal to the pylorus. Although it has a variable appearance, one relatively constant feature, which can help with identification, is a longitudinal fold of mucosa (or frenulum) below the papilla that forms a T configuration with the transverse fold (or hood) above the papilla. If not readily seen at the time of surgery, palpation of the medial duodenal wall will usually declare it as a firm nodule.

A true ampulla, the dilation of the common channel formed by the MPD and the CBD, is not always present. The ducts can join before traversing the duodenal wall as a common channel, and in this situation, a true ampulla is present in three quarters of cases. In contrast, a true ampulla is not present when the ducts join in the duodenal wall just prior to exiting or when the ducts do not join at all with two orifices in the duodenum and a septum between them.

The anatomy of the sphincter complex at the major duodenal papilla, named after Boyden and Oddi, is also variable. There are several sphincters of smooth muscle within the complex, and they function independently of the duodenal wall, reflecting the separate embryonic origin. This variation is in part explained by the obliquity of the path through the duodenal wall and in part by the variations related to the junction of the biliary and pancreatic ducts. In some cases, the sphincter complex extends beyond the duodenal wall. The length of the sphincter complex may vary from 6 to 30 mm, which probably explains why it is sometimes difficult to achieve a complete endoscopic sphincterotomy. The sphincter complex comprises four elements: a superior biliary sphincter, an inferior biliary sphincter (submucosal), a common ampullary sphincter,

Figure 6 Pancreatic tail and spleen.

Figure 7 The pancreatic ductal system comprises the main pancreatic duct or duct of Wirsung (1), the accessory pancreatic duct or duct of Santorini (2), and the duct to the uncinus process (4). The intrapancreatic portion of the common bile duct (3) is also shown.

and a pancreatic sphincter [see Figure 9]. The main blood supply to the major duodenal papilla is from the posterior superior pancreatic artery (PSPA), through a plexus formed with the choledochal vessels.

Dysfunction of the sphincter of Oddi is invoked as a cause of idiopathic biliary pain and acute pancreatitis. And although this can be measured using endoscopic retrograde manometers, the role of endoscopic or surgical sphincterotomy and/or pancreatic duct septotomy remains controversial. Anatomic variation may account for some of the conflicting results.

Arterial Anatomy of the Pancreas

The pancreas is the best perfused organ by weight in the body, next to the lactating breast, underpinning the high rates of protein synthesis for exocrine and endocrine function. The blood supply to the pancreas is from branches of the celiac trunk and the SMA, but there is considerable variation in pattern and nomenclature. The head of the pancreas and related duodenum is supplied by anterior and posterior pancreaticoduodenal arcades within the pancreatic substance and running parallel to the concave duodenal wall and arising from the GDA/common hepatic artery/celiac trunk and the IPDA/SMA, respectively [see Figure 10]. Thus, the PSPA arises as a branch of the GDA as it arises from the common hepatic artery along with the supraduodenal and retroduodenal arteries. The anterior superior pancreatic artery (ASPA) arises from the GDA as it terminates at the right gastroepiploic artery. The ASPA and PSPA anastomose with complementary arteries from the anterior inferior pancreatic artery (AIPA) arising from the SMA and the posterior inferior pancreatic artery (PIPA) also often arising

from the SMA as a common trunk, the IPDA. The IPDA is an important landmark in resection of the pancreatic head and should be formally ligated, and in so doing opens up the plane for dissection of the SMA, the important postero-medial margin of resection. It is notable that the IPDA can be single, double, or absent. The neck of the pancreas is supplied predominantly by the splenic artery arising from the celiac trunk and giving off the dorsal or great pancreatic artery (sometimes called the pancreatica magna) in its middle third, which often contributes a branch to the posterior pancreaticoduodenal arcade. The body and the tail of the pancreas are supplied by branches from the splenic artery along the superior border of the pancreas, and these branches connect with a transverse or inferior pancreatic artery, a collateral vessel that is a continuation of the dorsal pancreatic artery and runs within the pancreas toward the inferior margin. This arrangement is present about half of the time, whereas in 22% of cases, the inferior artery is absent, and in 25%, the body and tail are supplied only by branches from the inferior pancreatic artery. This latter situation increases the risk of pancreatic infarction if thrombosis or embolus of this single vessel occurs.⁴ Near the tail of the pancreas, the splenic artery branches for segmental supply of the pancreas. In up to one third of cases, the tail of the pancreas does not receive blood supply from the arteries of the pancreatic body. In this setting, the supply can be from the left gastroepiploic artery.

Anomalies of the hepatic arteries are of importance to the pancreatic surgeon, and there are several variants [see Figure 11]. Although formal preoperative invasive angiography is no longer indicated, staging computed tomography (CT) should include an arterial phase and arterial anomalies specifically examined for. A replaced or, of less concern,

Figure 8 Main variations in main pancreatic duct junction with bile duct.

an accessory right hepatic artery arising from the SMA presents the most frequent challenge, and these variations occur in up to 15% of the population.⁵ At the time of surgery, these can usually be detected behind the CBD (and often the portal vein) adjacent to the posterosuperior aspect of the pancreatic head. When arising from the origin of the SMA, the anomalous right hepatic artery does not usually traverse the substance of the gland, but when arising more distally, it can take a variable course through the pancreatic head and even the uncinate process. It may also anastomose with the posterior pancreaticoduodenal arcade and the IPDA. An anomalous left hepatic artery does not usually present a problem to the surgeon unless it arises from the right side of the SMA or the GDA. An anomalous middle colic artery can arise from the dorsal pancreatic artery or the IPDA and may pass through the head of the pancreas or between the head and the duodenum.

Another important vascular consideration relevant to resection of the pancreatic head is the challenge of celiac axis stenosis. This is most commonly secondary to compression by the median arcuate ligament or is attributable to atheromatous disease.⁶ In this setting, the liver is more reliant on supply via the GDA or an anomalous hepatic artery, if present. Although preoperative detection is usual, it is important to temporarily occlude the GDA before division to test that hepatic artery pulsation in the porta hepatis is not lost, by so doing. If this were the case, then a jump graft from the aorta may be required to ensure hepatic artery inflow.

Serious arterial bleeding following pancreatic surgery, both primary and secondary, is most commonly from the ligated GDA or IPDA. Secondary bleeding commonly follows a leak from the pancreatic anastomosis and may be heralded by sentinel bleeding. This is important as there may be time to undertake CT angiography and lifesaving embolization.⁷

Figure 9 The Sphincter of Oddi complex comprises the common ampullary sphincter (1), the inferior biliary sphincter (2), the superior biliary sphincter (3) and the pancreatic sphincter (4).

Venous Anatomy of the Pancreas

The homonymous venous anatomy usually parallels the arterial anatomy, but with the former taking a more superficial course. Venous drainage of the pancreas is into the portal, superior mesenteric, inferior mesenteric, and splenic veins [see Figure 12]. Related to the head of the pancreas are

the four pancreaticoduodenal veins that form the anterior and posterior arcades. There is almost invariably a tributary entering the portal vein at the level of the superior margin of the pancreatic head. In addition, the pancreatic head, neck, and uncinate process drain by a variable number of unnamed tributaries directly into the portal and superior mesenteric veins. An inferior or transverse pancreatic vein can be present and drains into the splenic vein or the inferior mesenteric vein.

Venous bleeding during pancreatic surgery can occur from multiple sites, but it is worth mentioning the most common. The gastroduodenal vein arises from the right gastroepiploic vein, crosses the pancreatic neck, and receives the anterior superior pancreaticoduodenal vein and a variable number of venous tributaries from the transverse mesocolon. Troublesome bleeding can occur from this confluence unless these veins are specifically identified and divided. There is also a rare risk of bleeding if the posterior superior pancreaticoduodenal vein directly enters the anterior aspect of the portal-superior mesenteric vein, and is vulnerable when the plane between the pancreas and the subjacent veins is established. The left gastric (coronary) vein from the lesser curve of the stomach passes alongside the superior margin of the pancreas to enter the splenic ($\approx 70\%$) or the portal ($\approx 30\%$) veins.

The resection of a pancreatic head mass sometimes requires resection of a portion of the portal or superior mesenteric veins and reconstruction by primary closure, patch, or graft. Segmental resection of one of the two first-order branches of the SMV (jejunal or ileal) may be performed without venous reconstruction if mesenteric venous flow is preserved to the remaining first-order tributary [see Figure 13].⁸

Lymphatic Drainage of the Pancreas

Lymph arises in the interstitium of the exocrine pancreas and collects within variable fine-walled intralobular lymphatic vessels that coalesce to become interlobular lymphatics. In contrast to the lobules, no lymphatic vessels have been identified within the islets of Langerhans. Lymph appears to be taken up by lymphatic ducts at the periphery of the islets. The intralobular lymphatics initially drain in the same direction as the ducts, but the flow then diverges toward the surface of the gland, in contrast to the ducts that drain toward the center of the gland. On the surface of the pancreas, the lymphatic vessels form a superficial network that converges toward lymph nodes, often at the periphery of the gland. Thus, the lymphatic drainage of the pancreas is centrifugal to peripheral lymph nodes. Efferent vessels from these nodes eventually empty into the thoracic duct.

Understanding the pattern of lymph node drainage is important in pancreatic cancer surgery, both for accurately staging the disease and for achieving clearance to reduce the risk of locoregional recurrence. It has not been possible to demonstrate survival benefit from extended lymph node excision, probably because of the rapid clearance of lymph into the thoracic duct.⁹ Formal reporting of lymph nodes according to the American Joint Committee on Cancer does not require anatomic division of regional lymph nodes.¹⁰ The superior lymphatic vessels are in close association with the splenic artery and vein, running along the upper border of the pancreas. The tail and left side of the pancreas drain toward lymph nodes in the hilum of the spleen, whereas the right side of the body and neck of the pancreas drain toward lymph nodes located near the upper border of the head of the pancreas. Both anterior and posterior aspects of the upper half of the pancreas drain to the superior lymphatic

vessels. There is a similar network of inferior lymphatic vessels that runs with the transverse pancreatic artery and vein. As with the superior lymphatic vessels, the tail and left side of the body drain toward lymph nodes in the hilum of the spleen, and the remainder of the pancreas drains toward nodes surrounding the head. There is a lack of clear demarcation within the regions of the pancreas that drain toward the spleen, those that drain toward the head of the pancreas, and those that drain to the superior or inferior vessels. This is because lymphatics richly anastomose and ramify together, and flow direction may be affected by local pressure changes. It is therefore difficult to accurately predict the direction of lymph drainage from carcinomas within the pancreas.

The external lymphatic network draining the head of the pancreas forms anterior and posterior vessels, which lie adjacent to the pancreaticoduodenal arteries and veins. These are situated in the groove between the duodenum and pancreas. In parallel with the blood vessels, there are four main lymph vessels that drain the head: anterior superior, posterior superior, anterior inferior, and posterior inferior. There is another route for lymph drainage of the head running with the GDA.

Although there is agreement on the general pattern of drainage, there is a lack of consensus on the nomenclature for regional nodes. The original descriptive classification was by Evans and Oschner in 1954,¹¹ and it was updated by Pansky in 1990.¹² The Japanese have provided more recent detailed studies and a numerical classification of peripancreatic lymph nodes [see Figure 14].¹³ There are two broad groups of lymph nodes: those forming a ring around the pancreas and those related to the aorta and its branches. Located in the hilum of the spleen are the splenic nodes, which lie in close proximity to the tail of the pancreas. These nodes drain lymph from the tail and left side of the body via the left superior and inferior external lymphatics. Within the gastrosplenic ligament is a group of related nodes, the gastrosplenic lymph nodes. Although these predominantly drain part of the stomach, they also receive some lymph from the tail and left side of the body of the pancreas. Along the splenic artery lie scattered nodes that drain the upper portions of the pancreas and some of the stomach. In the region of the upper part of the head of the pancreas are several small groups of nodes, which drain the anterior and posterior aspects of the upper head. The nomenclature of these subgroups is inconsistent between authors. They include gastroduodenal, pyloric, infrapyloric, and retropyloric groups. The hepatic group lies alongside the CBD and common hepatic artery. The pancreaticoduodenal nodes, divided into four subgroups, as with the vascular arcades, lie close to the blood vessels and lymphatics of the same name. The upper nodes drain the upper portions of the head, and the lower nodes drain the lower portions of the head. The infrapancreatic group of nodes completes the ring around the pancreas. These nodes lie along branches of the dorsal pancreatic artery. Evans and Oschner also included a mesocolic group of nodes, which lies within the transverse mesocolon.¹¹

The lymph nodes associated with the aorta have been divided into preaortic (in front of the aorta), lateral aortic (left of the aorta), and interaortocaval (between the aorta

Figure 14 Peripancreatic lymph nodes.

and inferior vena cava) groups. These nodes lie between the celiac trunk and SMA. The preaortic nodes have two subgroups, the celiac group and the superior mesenteric group, which surround the vessels of the same name.

Nerve Supply of the Pancreas

Innervation of the pancreas occurs by the splanchnic nerves (sympathetic) and the vagus nerves (parasympathetic). Both contain efferent vasomotor fibers to the pancreatic acini, ducts, and blood vessels and afferent pain fibers. The former is critical to both exocrine and endocrine function, and the latter has significance because pain is an important feature of both benign and malignant pancreatic diseases. Pancreatic pain is multifactorial, and a full discussion is beyond the scope of this chapter, but factors include perineural infiltration by cancer, damage to perineurium, inflammatory mediators, ductal hypertension, and compartment syndrome. Pancreatic pain is poorly localized. Like other foregut structures, pain is most often referred to the epigastrium and to the midback. The interruption of pain is an important therapeutic goal, but the variety of methods used (including surgical, thoracoscopic, radiologic, and endoscopic chemical approaches) reflects the less than satisfactory response to neural ablation techniques. The mainstay of analgesia remains pharmacology.

The preganglionic sympathetic nerves are from the greater (T5-T10), the lesser (T9-T11), and sometimes the least splanchnic nerves. These pierce the diaphragm to reach ganglia within neural plexi associated with the origin of the celiac trunk and SMA. Postganglionic nerve fibers arising from

neurons in these ganglia reach the pancreas by accompanying branches of these arteries as periarterial plexi.

The preganglionic parasympathetic nerves, from the celiac division of the posterior vagal trunk, synapse with ganglia within the pancreas. The postganglionic fibers terminate at the pancreatic islet cells. Innervation of the islet cells is almost exclusively from the parasympathetic side, and fibers frequently synapse with acinar cells before reaching the islet cells, suggesting neural coordination between exocrine and endocrine components. Three types of neural termination with islets are recognized,¹⁴ but no selective termination is recognized with any particular islet cell type.

Arising in the pancreas, the afferent (visceral) pain fibers pass cranially through the celiac plexus to their cell bodies in the dorsal root ganglia within the splanchnic nerves, crossing to the spinal nerves by way of the white communicating rami and at a spinal level comparable to the preganglionic sympathetic fibers.

Physiology of the Exocrine Pancreas

The pancreas was not elected an organ until 1850, when Claude Bernard demonstrated that it had a function, namely, the production of digestive enzymes. The functional unit of the exocrine pancreas is the acini (meaning “cluster of grapes”), the collection of acinar cells responsible for the secretion of digestive enzymes, pancreatic fluid, and electrolytes via the ductal network.

Digestive enzymes are synthesized in the acinar cell endoplasmic reticulum, packaged by the Golgi apparatus in

zymogen granules, and released at the cell apex by exocytosis into the ductal system [see Figure 15]. The ductal epithelial cells are a continuous layer with tight junctions. Significant defenses exist to prevent premature intra-acinar enzyme activation (a key feature of acute pancreatitis), including compartmentalization in the granules, separation from lysozymes, trypsin inhibitors, and antiproteases. Activation of the enzymes normally occurs by cleavage of trypsinogen to trypsin by intestinal enteropeptidase, which in turn activates a cascade of the other digestive enzymes.

The exocrine pancreas secretes 800 mL/day or more of alkaline fluid, with a high HCO_3^- content (approximately 115 versus 25 mEq/L in plasma). Bicarbonate is generated within the ductal cells through the action of carbonic anhydrase and expelled into the lumen in exchange for chloride. Bile and intestinal juices along with pancreatic secretions help neutralize the gastric acid, raising the pH of the duodenal lumen toward 7.0.

Control of the exocrine function of the pancreas is via the hormones gastrin, cholecystokinin (CCK), and secretin, which are secreted by cells in the stomach and duodenum in response to distention and/or food and which cause secretion of pancreatic juices. Secretin acts via intracellular cyclic adenosine monophosphate (cAMP) in the centroacinar cells to produce copious secretion of very alkaline pancreatic juice that has low levels of digestive enzymes. CCK acts on the acinar cells to cause the release of zymogen granules and production of pancreatic juice rich in enzymes but low in volume. Its effect is mediated by phospholipase C. Like CCK, acetylcholine acts on acinar cells via phospholipase C to cause discharge of zymogen granules, and stimulation of the vagi causes secretion of a small amount of pancreatic juice rich in enzymes. There is evidence for vagally mediated conditioned reflex secretion of pancreatic juice in response to the sight and/or smell of food.

Approximately 80 to 90% of the pancreas can be surgically removed without producing pancreatic exocrine insufficiency. And if, by virtue of prior pancreatic disease, resection produces exocrine insufficiency, enzyme replacement is effective.

The Achilles heel and ever-present risk of pancreatic surgery is a leak from a pancreatic anastomosis or a pancreatic transection margin. The leak of pancreatic enzymes has dire potential consequences, including intra-abdominal collections, pancreatic fistulae, gastric and intestinal ileus, portal vein thrombosis and hypertension, pseudoaneurysm, and bleeding. The risk factors for leak have been well documented and include patient factors (malnutrition, age), pancreatic factors (soft gland, small duct, fatty replacement of pancreas), and surgeon factors (experience, precision, and technique).

Physiology of the Endocrine Pancreas

The pancreatic islets of Langerhans were discovered in 1869, and insulin was discovered in 1921. There are 1 to 2 million islets, which together weigh about a gram, and these are dispersed throughout the pancreas [see Figure 16]. These ovoid clusters of polyhedral cells are more plentiful in the tail than in the body and head and represent only 2% of the pancreatic mass.¹⁵ The perfusion of the islets is much greater than that of the acinar tissue, with each islet supplied by one or two arterioles and all the islet cells are in close proximity to fenestrated capillaries, which empty directly into the acinar capillary plexus.

The cells in the islets are divided into different types based on their immunostaining properties and morphology: A, B, D, E, and F cells. A cells secrete glucagon, B cells secrete insulin, D cells secrete somatostatin, E cells secrete ghrelin, and F cells secrete pancreatic polypeptide. B cells, which are

Figure 15 Microstructure and control of the exocrine pancreas.

Figure 16 Microstructure and control of the endocrine pancreas.

the most abundant, account for 60 to 75% of the cells in the islets and are generally located in the center of each islet. They tend to be surrounded by A cells, which make up 20% of the total, and the less common D and F cells. The islets in the tail, the body, and the anterior and superior parts of the head of the human pancreas have many A cells and few, if any, F cells in the outer rim. The A cell-rich islets arise embryologically from the dorsal pancreatic bud, and the F cell-rich islets arise from the ventral pancreatic bud.

The importance of the endocrine pancreas lies in the fact that insulin plays a central role in the regulation of energy metabolism. Insulin is anabolic, increasing the storage of glucose, fatty acids, and amino acids. Glucagon is catabolic, mobilizing glucose, fatty acids, and the amino acids from stores into the bloodstream. These two hormones are reciprocally secreted in most circumstances. In the fed state, insulin stimulates the transport of glucose into tissues (to be consumed as fuel or stored as glycogen), the transport of amino acids into tissues (to build or replace protein), and the transport of fatty acids into tissues (to provide a depot of fat for future energy needs). In the fasting state, insulin secretion decreases and glucagon secretion increases. Liver glycogen stores, followed later by protein and fat stores, are mobilized to produce glucose. Ultimately, most nutrient needs are provided by fatty acids mobilized from fat stores.

The exocrine acinar tissue receives arterialized blood from two sources, directly and indirectly from the endocrine pancreas. The functional significance of the portal system

(insuloacinar axis), linking the exocrine and exocrine organs of the pancreas, is not well understood but suggests that the former may modulate the latter.

The islets contain many nerve endings. The autonomic neurotransmitter acetylcholine augments insulin and glucagon release, and noradrenaline inhibits glucose-induced insulin release. Both also modulate somatostatin and pancreatic polypeptide secretion. Islets can also influence each other through paracrine and autocrine communication. The paracrine effects of insulin are to activate beta cells and inhibit alpha cells; glucagon activates alpha cells, which activate beta and delta cells, and somatostatin inhibits alpha and beta cells.

Insulin excess causes hypoglycemia, which leads to convulsions and coma. Insulin deficiency, either absolute or relative, causes diabetes mellitus (chronic elevated blood glucose). Glucagon deficiency can cause hypoglycemia, and glucagon excess makes diabetes worse. Somatostatin plays a role in the regulation of islet cell secretion, and excess production causes hyperglycemia and other manifestations of diabetes. Pancreatic polypeptide is probably concerned primarily with the regulation of HCO_3^- secretion to the intestine. Glucagon, somatostatin, and possibly pancreatic polypeptide are also secreted by cells in the mucosa of the gastrointestinal tract.

Insulin causes hypokalemia as it increases the activity of Na^+ , K^+ -ATPase in cell membranes, with K^+ pumped into cells. Infusions of insulin and glucose significantly lower the plasma K^+ level in normal individuals and are an effective

way to treat hyperkalemia in patients with renal failure. Diabetic patients undergoing surgery require added potassium when insulin and glucose are given.

The panoply of neuroendocrine neoplasia arising from the islet cells partly reflects the different cell types, and these tumors can be nonfunctioning (no detectable secretion), of indeterminate malignant potential, undifferentiated, multifocal, and sometimes undetectable. These factors challenge diagnosis, and surgical treatment must be tailored, ensuring both clearance of the tumor and preservation of pancreatic function where possible. The surgical options include enucleation, median segment resection, spleen-preserving resection of the pancreas tail and/or body, distal pancreatectomy, subtotal pancreatectomy, and pancreaticoduodenectomy. It is unusual for a standard pancreatic resection to result in pancreatic endocrine deficiency. For instance, insulin deficiency does not occur unless more than 80% of the islet cell mass has been removed or the remaining pancreas is diseased, as in chronic pancreatitis, with a loss of islet cell mass or function.

14 ANATOMY AND PHYSIOLOGY OF THE COLON, APPENDIX, RECTUM, AND ANUS

Laura E. Fischer, MD, MS, and Charles P. Heise, MD, FACS

The large intestine is composed of the cecum, appendix, ascending colon, transverse colon, descending colon, and sigmoid colon. It plays a role in immune function, nutrient absorption, and water and electrolyte absorption and secretion, whereas the rectum and anus function in the maintenance of continence and elimination of waste through defecation.

Colon

ANATOMY

The colon is composed of the cecum, ascending colon, transverse colon, descending colon, and sigmoid colon and is approximately 0.9 to 1.5 meters long. The wall of the colon is made up of five distinct layers: mucosa, submucosa, circular muscle, longitudinal muscle, and serosa. The longitudinal muscle layer is divided into three distinct bands, named the taenia coli. The taenia coli converge and become circumferential proximally at the appendix and distally at the rectum; this convergence arbitrarily defines these structures. The haustra are the saccular protrusions of circular muscle between the taenia. The intraperitoneal colon is covered with serosa, whereas the retroperitoneal portions are not.¹ The muscular layers consist of smooth muscle cells connected by gap junctions that allow transmission of electrical signals and several types of interstitial cells of Cajal (ICC).²

The cecum is the first part of the large intestine and is located in the right lower quadrant of the abdomen in the iliac fossa in cases of normal embryologic intestinal rotation. The terminal ileum enters the cecum at the ileocecal valve; it enters obliquely and partially invaginates into it. The cecum is the widest portion of the colon at approximately 7.5 cm in both length and width and is therefore the most prone to perforation. When the cecum is distended, the folds of the ileocecal valve close, preventing reflux of cecal contents into the terminal ileum.¹

The ascending colon lies between the cecum and the transverse colon. The majority of the ascending colon is secondarily retroperitoneal. The transverse colon is the largest and most mobile portion of the large bowel and is defined proximally by the hepatic flexure and distally by the splenic flexure. The mesentery of the transverse colon, called the transverse mesocolon, often loops down and can adhere to the posterior border of the omentum. The descending colon again becomes retroperitoneal from the splenic flexure to the left iliac fossa, where it is continuous with the sigmoid colon. The sigmoid colon is characterized by an S-shaped loop and is of variable length. It extends from the iliac fossa

to the termination of the taenia coli, indicating the rectosigmoid junction. It has a long mesentery and significant freedom of movement, making it prone to volvulus.¹

Innervation

The colon receives innervation from four types of neurons: enteric, parasympathetic (excitatory), sympathetic (inhibitory), and intrinsic and extrinsic sensory² [see Figure 1].

The enteric nervous system (ENS) consists of two ganglionated plexuses and is estimated to contain more neurons than the spinal cord.³ The outer, myenteric (Auerbach) plexus lies between the longitudinal and circular muscle layers of the colon and contains motor neurons, which innervate the smooth muscle.^{2,3} The inner, submucosal (Meissner) plexus lies within the submucosal connective tissue and appears to be involved in mucosal functions such as secretion and blood flow.^{2,3}

The cecum, ascending colon, and proximal transverse colon receive modulatory nerve fibers traveling from the superior mesenteric plexus that carry both sympathetic and parasympathetic nerves. Parasympathetic innervation arises from the vagus nerve, which sends preganglionic cholinergic fibers, which synapse on ganglia within the enteric plexuses. Sympathetic innervation arises from the distal cervical to the third lumbar segments of the spinal cord. These nerve fibers enter the paravertebral sympathetic ganglia and emerge as splanchnic nerves, which travel through the preaortic ganglia, giving rise to the postganglionic adrenergic fibers supplying the colonic musculature. The descending and sigmoid colons receive parasympathetic fibers from the pelvic splanchnic nerves originating at S2, S3, and S4, whereas the sympathetic supply is from the lumbar portion of the sympathetic trunk and the superior hypogastric plexus.¹ The myenteric and submucosal plexuses also contain intrinsic sensory neurons, called intrinsic primary afferent neurons, which are sensitive to chemical and mechanical stimulation and synapse with ENS interneurons and myenteric motor neurons to regulate blood flow, secretion, and motility.^{2,4} There are two types of primary, extrinsic afferent neurons: vagal afferents sense thermal and chemical stimuli and regulate autonomic function, whereas spinal afferents sense mechanical stimuli and contribute to pain sensation.⁴

Blood Supply

The colon is supplied by branches of the superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA) [see Figure 2]. The cecum, ascending colon, and proximal transverse colon are part of the embryonic midgut and are therefore supplied by branches of the SMA. The distal transverse colon, descending colon, and sigmoid colon are part of the embryonic hindgut and are supplied by branches of the IMA.⁵ The cecum is supplied by the ileocolic artery, the

Financial disclosure information is located at the end of this chapter before the references.

Figure 1 The layers of the colonic wall and the various components of the enteric nervous system and its interactions with the central nervous system. The two ganglionated plexuses, the submucosal (Meissner) plexus and the myenteric (Auerbach) plexus, are seen. Adrenergic, inhibitory input is via sympathetic afferent input, whereas cholinergic, excitatory stimulus is via parasympathetic afferent input. Sensory input begins with the enterochromaffin cells, which sample the luminal environment and transmit that information via intrinsic and extrinsic sensory neurons using serotonin as a messenger. 5-HT = Serotonin, NE = Norepinephrine, ACh = Acetyl Choline.

terminal branch of the SMA. Venous drainage is by the ileocolic vein into the superior mesenteric vein. The ascending colon is supplied by the ileocolic and right colic arteries, and the transverse colon is supplied by the middle colic artery. The ileocolic artery is the most constant anatomically, whereas the right and middle colic arteries are variable and may be missing in up to 25% of the population.⁵ The descending colon is supplied by the left colic artery, whereas the sigmoid colon is supplied by the left colic and superior sigmoid arteries, which are branches of the IMA. The veins of the colon mirror the arterial supply, except for the inferior mesenteric vein, which drains into the splenic vein.¹

The terminal branches of arteries supplying the colon form collateral branches with each other via the marginal artery of Drummond, which is complete in 15 to 20% of the population.¹ This major collateral arcade is located within the mesentery and lies about 2 to 3 cm from the mesenteric border of the bowel. The arc of Rioloan is an additional set of collateral branches that lie more centrally within the mesentery and form a connection between the middle colic and left colic arteries. The splenic flexure is considered a “watershed” area of variable arterial blood supply: in 89% of the population, the splenic flexure is supplied by the IMA, and in 11%, the supply is via the SMA. Limited collateral blood supply in this area makes it prone to ischemia.⁵

Lymphatic Drainage

The lymphatic drainage of the colon originates in the muscularis mucosa. Lymph nodes are found along the bowel wall, the inner mesenteric border of the bowel, and the named mesenteric vessels and adjacent to the origin of the superior and inferior mesenteric arteries, called the epicolic, paracolic, intermediate, and main lymph nodes, respectively. The lymphatic drainage of the cecum is via the ileocolic nodes that lie along the ileocolic artery and drain into the superior mesenteric lymph nodes. The ascending and transverse colons drain into the superior mesenteric lymph nodes that follow the supplying arteries. The descending and sigmoid colons drain along their vascular supply into the inferior mesenteric lymph nodes, although the splenic flexure can sometimes drain into the superior mesenteric basin.¹

PHYSIOLOGY

The colon has several important functions: mixing and propagation of luminal contents, water and electrolyte secretion and absorption, and salvage of nutrients not absorbed by the small intestine through bacterial metabolism of carbohydrates.

Motility

The circular and longitudinal muscle layers of the colon work together to accomplish mixing of fecal material and

Figure 2 The blood supply to the colon. Major branches from the superior and inferior mesenteric vessels are depicted. In addition, the marginal artery of Drummond can be visualized as the collateral arcades in the distal mesentery.

propagation to the anorectum for evacuation. The three longitudinal muscle bands forming the taenia cause the circular muscle to bulge outward into pockets, which foster mixing. Conversely, when the circular muscle of the colon contracts, deep folds protrude into the colonic lumen, greatly reducing its diameter.⁶

Colonic motility is irregular and includes both tonic and phasic components.⁶ Basal motor activity is segmental, of low amplitude, with contractions occurring singly or in bursts and in random sequence⁷ [see *Figure 3*]. Motor patterns differ between the right colon and left colon: orad and anad peristalsis facilitate mixing in the ascending and proximal transverse colons, whereas the distal transverse and descending colons exhibit only caudal peristalsis with contracting circular rings that travel distally.⁶ Motor activity in the colon exhibits diurnal variation: activity is minimal during sleep but increases dramatically on awakening. Motor activity also starts promptly with food ingestion and lasts up to several hours after a meal⁷; postprandial contractile activity is associated with mass movement of fecal contents and is known as the gastrocolic reflex. High-amplitude propagated contractions (HAPCs), consisting of a pressure

wave greater than 50 mm Hg, propagate fecal contents over several segments, often producing an urge to defecate, and occur on average six times per day.^{6,7} The colocolonic reflex describes the phenomenon of colonic relaxation with rectal distention, which is mediated by the ENS independent of regulatory efferent input.⁶

Circumferential stretch has been shown to induce peristalsis, whereas longitudinal stretch inhibits peristalsis via nitric oxide (NO) release in animal models.⁸ Colonic tone, another important factor in motor regulation, is increased in the postprandial period and associated with a decrease in storage capacity and the production of a pressure gradient that moves intraluminal contents to areas of lower pressure. Additionally, colonic motility is significantly affected by its intraluminal contents. In the proximal colon, short-chain fatty acids (SCFAs) are produced through carbohydrate metabolism by bacteria and have an excitatory effect, although higher concentrations of SCFAs seem to have an inhibitory effect on colonic motility.⁶

Basal colonic contractions are controlled by pacemaking electrical signals generated by the ICC, a continuous network of electrically coupled cells.⁹ ICC networks extend

Figure 3 The various types of colonic motility: bidirectional mixing in the proximal colon, unidirectional propagation in the distal colon, and high-amplitude propagated contractions (HAPCs) over several segments. Colonic activity varies with time of day and is most evident on awakening and after meals.

along all portions of the gastrointestinal tract that are involved in phasic contractions, including the colon. These cells are coupled to smooth muscle and spontaneously generate and propagate slow waves through voltage-dependent Ca^{2+} channels.⁹ The ENS provides direct neuronal control of motility, whereas further modulation is effected by the sympathetic, parasympathetic, and extrinsic afferent sensory pathways.² The extrinsic spinal sensory neurons mediate sensation and activate sympathetic and parasympathetic pathways.² Normal colonic motility is maintained even if sympathetic and parasympathetic input is disrupted due to the intrinsic, integrated functionality of the ENS.¹⁰

Neurohormonal Influences

The regulation of colonic activity is quite complex, and numerous modulatory agents have been identified in recent years. Motor activity is regulated by muscarinic, α -2 adrenergic, serotonergic 5-hydroxytryptamine₃ (5-HT₃), and nitrergic mechanisms.¹¹ In addition to the sympathetic and parasympathetic pathways, nonadrenergic, noncholinergic (NANC) neurotransmitters also play an important role in modulating colon motility. Cholecystokinin (CCK), motilin, serotonin, and gastrin excite intestinal contractions. Excitatory neuropeptides include substance P, neurotensin, and γ -aminobutyric acid (GABA), whereas inhibitory neuropeptides include secretin, glucagon, vasoactive intestinal peptide, neuropeptide Y, and NO.^{12,13} There is evidence that NO is a major NANC neurotransmitter in the colon that causes inhibition of smooth muscle contractions.^{12,13}

Sensation, peristalsis, and secretion in the colon are mediated through the release of 5-HT, or serotonin, from enterochromaffin cells in the mucosal layer and both intrinsic and extrinsic sensory neurons in the ganglionated plexuses. 5-HT₃ receptors are found within both the central nervous system and the ENS, where they mediate transmission of sensation from the gut to the brain, but 5-HT_{1P} and 5-HT₄ receptors, which mediate peristalsis and secretion, are found only within the ENS. This differential distribution of receptors has led to the development of targeted therapies for colonic dysfunctional disorders.¹⁰

The most important dietary stimulant of colonic motility is fat through the mediator CCK. CCK₁ receptors are predominantly found within the myenteric plexus and the longitudinal muscle layer. The endogenous release of CCK is associated with the gastrocolic reflex, HAPCs, and pain sensation; CCK receptor antagonists significantly decrease these effects in vivo.¹⁴

Electrolyte and Water Secretion and Absorption

The colon is the final site at which electrolyte and water secretion and absorption can be performed in the gastrointestinal tract. Traditionally, surface epithelium has been associated with absorption, whereas colonic crypt cells were associated with secretion. However, both types of cells can perform either function.¹⁵ There are three main types of cells: columnar epithelial cells, mucus-secreting goblet cells, and enterochromaffin cells [see Figure 4]. The two major electrolytes absorbed by the colon include sodium (Na^+) and chloride (Cl^-) via electroneutral, luminal Na^+/H^+ and $\text{Cl}^-/\text{HCO}_3^-$ exchangers. Na^+/H^+ exchange occurs in both surface and crypt cells and is tightly coupled to $\text{Cl}^-/\text{HCO}_3^-$ exchange. There are several identified types of cell surface exchangers, each with a different regulatory profile based on location within the colon.¹⁵ The distal colon has an additional electrogenic exchanger, the epithelial Na^+ channel (EnaC). A large electrochemical gradient favors Na^+ transport into the apical cell, accompanied by Cl^- as the anion. Na^+ is then excreted at the basolateral membrane by Na^+/K^+ ATPase and Cl^- by Cl^- channels or $\text{Cl}^-/\text{HCO}_3^-$ exchange.¹⁵ This uptake of NaCl is highly regulated with multiple feedback mechanisms, including upregulation of absorption by aldosterone. Water absorption, an important function of the colon that osmotically follows the absorption of Na^+ and Cl^- , is approximately 1.5 L per day.¹⁵

Figure 4 Electrolyte absorption and secretion are mediated by a complex system of electroneutral and electrogenic transporters. Sodium and chloride are primarily absorbed, whereas potassium and bicarbonate are primarily excreted by the colon. Water absorption, which is stimulated by short-chain fatty acids, also occurs in the colon and often follows NaCl absorption. AE = anion exchanger; ATP = adenosine triphosphate; CFTR = cystic fibrosis transmembrane regulator; DRA = Cl⁻/HCO₃⁻ exchanger SLC26A3 ("downregulated in adenoma"); ENaC = epithelial Na⁺ channel; NHE = Na⁺/H⁺ exchanger; NKA = Na⁺/K⁺ ATPase; NKCC1 = Na⁺-2Cl⁻-K⁺ cotransporter.

Secretion of electrolytes, mainly potassium (K⁺) and bicarbonate (HCO₃⁻), also occurs in the colon in a delicate balance to maintain homeostasis. The apical secretion of KCl is balanced by basolateral absorption of Na⁺, K⁺, and Cl⁻ via the Na⁺-2Cl⁻-K⁺ cotransporter type 1 (NKCC) protein. Cl⁻ is secreted via the cystic fibrosis transmembrane regulator (CFTR) protein and calcium-activated Cl⁻ channels. K⁺ is secreted by at least two different types of apical channels, which are upregulated by aldosterone and glucocorticoids in parallel with Na⁺ absorption.¹⁵ HCO₃⁻ secretion has specific roles, including pH control of the surface microenvironment and influence on surface mucus production.¹⁶ The expression of colonic HCO₃⁻ transporters is highly segmental: HCO₃⁻ and Cl⁻ secretion and absorption are higher in the proximal colon.¹⁶

Absorption and secretion are regulated by neurotransmitters released from the submucosal plexus as well as hormones and paracrine substances. Small gaseous molecules, such as NO, hydrogen sulfide (H₂S), and carbon monoxide (CO), also have a role in the regulation of colonic ion transport.¹⁷ NO acts through the cyclic guanosine monophosphate pathway and induces Cl⁻ secretion. H₂S relaxes smooth muscle and induces anion secretion across the apical epithelium. CO, a metabolite from the degradation of heme, also induces Cl⁻ and HCO₃⁻ secretion.¹⁷

SCFAs, primarily acetate, propionate, and butyrate, are the major anions in stool and are synthesized by the bacterial fermentation of carbohydrates not absorbed by the small intestine.¹⁸ SCFAs are absorbed by the colonic epithelium and stimulate the absorption of water in a Na⁺-dependent manner,¹⁸ facilitate the absorption of electrolytes, and reduce the osmotic load of carbohydrates.¹⁹ SCFAs are the primary fuel source for colonocytes and have been estimated to make up 5 to 15% of daily energy requirements.^{20,21} They additionally help regulate epithelial cell proliferation and differentiation.¹⁸ A recent study suggests that butyrate may exert a variety of effects, including inhibition of inflammation

and carcinogenesis, reinforcement of the mucosal defense barrier, and decreasing oxidative stress.²¹

Appendix

ANATOMY

The vermiform appendix is a blind intestinal diverticulum that arises from the posteromedial aspect of the cecum approximately 2 cm inferior to the ileocecal valve.^{1,22} The opening of the appendix is partially covered by a fold of mucosa called the valve of Gerlach.²³ It can range from approximately 6 to 10 cm in length, with an average of 9 cm,^{1,23} and has a short mesentery, the mesoappendix, which is derived from the mesentery of the terminal ileum.¹ Whereas the base of the appendix is in a relatively constant position, the tip of the appendix is highly variable, leading to differing presentations of pathology. The various positions of the appendiceal tip include preileal, postileal, pelvic, promontoric, subcecal, retrocecal, and paracolic locations,^{22,23} with the large majority (65%) in the retrocecal location.²⁴ The musculature of the appendix resembles the cecum and includes both circular and longitudinal layers.

Innervation

Appendiceal innervation mirrors that of the proximal colon. Parasympathetic innervation arises from the vagus nerve. Sympathetic innervation arises from thoracic and lumbar spinal cord via the paravertebral sympathetic ganglia.

Vasculature

The appendix is supplied by the appendicular artery, a branch of the ileocolic artery. It is drained by the ileocolic vein.

Lymphatic Drainage

The appendix contains a large number of lymph follicles within the submucosa, which peak in concentration in the

10 to 20 years age group and decline in number with age.²² The lymphoid system of the appendix drains via the mesoappendix to empty into the ileocecal nodes.²²

PHYSIOLOGY

Immunology

The definitive role of the appendix remains unclear; however, there is consensus that the appendix is not merely a vestigial organ but rather has an important immunologic function acting as a secondary lymphoid organ.

Studies in rabbits have indicated that the appendix is not only important for mucosal gut immunity but is also the primary site of antibody diversification.²⁵ The removal of the appendix from neonatal rabbits severely depletes the amount of intestinal IgA, IgM, and IgG, as well as IgA-producing plasma cells, supporting the concept that the appendix is involved in the early development of gastrointestinal mucosal immunity.²⁶ Other studies have shown that antibody diversification occurs in the lymphoid tissue of young rabbits²⁷ and that the appendix evolves into a secondary lymphoid organ as the rabbit matures.

Lymphoid tissue is abundant within the appendix and comprises a substantial portion of the MALT (mucosa-associated lymphoid tissue) system. Appendix-derived mesenchymal stem cells have been isolated from human appendices, indicating that the appendix plays a role in the development of mucosal immune cells in humans.²⁸ Additionally, stem cells isolated from the appendix have been shown to produce extrathymic T cells.²⁹ The removal of the appendix significantly lowers the level of secretory IgA in the serum, and this effect lasts from 3 months to 3 years.³⁰ The immune function of the appendix appears most prominent between the ages of 10 and 20, after which it wanes until lymph follicles disappear around age 60.²² Recent studies also indicate that the appendix may have an antiinflammatory, cardioprotective effect in childhood and early adulthood.^{31–33} Together these data suggest that the appendix may play a partial yet currently undefined role in overall immunologic function.

Rectum

The most distal portion of the gastrointestinal tract is the rectum and anal canal. Although comprising only a small portion of the overall anatomy, this region and its interactions are quite complex in their functioning to maintain fecal continence.

ANATOMY

The rectum begins with a coalescence of the taenia coli of the sigmoid colon to become the outer longitudinal muscle. The rectum is generally considered to be 12 to 18 cm in length and is contained within the pelvis. It is often divided into thirds due to the three visualized endoluminal folds (two on the left and one on the right) called the valves of Houston. The rectum ends with its exit through the pelvic floor musculature to begin the anal canal. The peritoneal reflection variably exists along the course of the rectum, making the anterior distal portion and the entire posterior rectum extraperitoneal. The rectum and mesorectum are

encompassed within the visceral layer of the endopelvic fascia. This fascia propria makes up the mesorectal envelope. The parietal layer of endopelvic fascia encompasses the sacrum.³⁴ Anteriorly, a potential plane exists between the fascia propria of the rectum and a thin fascial covering (Denonvillier fascia) of the prostate and seminal vesicles in males or rectovaginal septum in females.³⁵ Posteriorly, the rectum overlies the endopelvic fascia covering of the sacrum, which encompasses the sacral nerves, middle sacral artery, and presacral veins. Just cephalad to the coccyx, the two endopelvic fascial layers fuse to form the Waldeyer fascia (rectosacral fascia)³⁶ [see Figure 5]. Laterally, attachments exist, often referred to as the lateral rectal ligaments (stalks). Although it is often reported that these ligaments contain the middle rectal (hemorrhoidal) arteries, it has been shown that arteries exist here only 20% of the time.³⁷ More likely, these ligaments generally contain nerve branches stemming from the pelvic plexuses below the peritoneal reflection and onto the mesorectum.³⁸

Innervation

The organization of local rectal myenteric and submucosal plexuses mirrors that of the colon, as described above. The rectum receives parasympathetic innervation from the ventral roots of S2–S4 via the pelvic plexus, where sympathetic and parasympathetic nerve fibers mix.^{2,39} Sympathetic innervation arises from the thoracolumbar sympathetic ganglia, which enter the preaortic plexus as the inferior mesenteric nerves and then extend caudally to the mesenteric plexus. The fibers then branch into the hypogastric nerves at the upper rectum and join the parasympathetic nerve branches.^{34,39} As the mixed nerve fibers enter the rectum, a portion of them form thick bundles that transmit the electrical input up and down the distal colon.² Sensory innervation of the rectum is via spinal afferent neurons with cell bodies in the lumbar and sacral dorsal root ganglia.

Blood Supply

The blood supply to the rectum comes from the superior rectal (hemorrhoidal) artery and, when they exist, the middle rectal (hemorrhoidal) arteries, resulting in a rich intramural anastomotic network.⁵ The superior rectal artery is a continuation of the IMA, whereas the middle rectal artery begins from the hypogastric or inferior vesicle arteries and runs anterolaterally to the lower third of the rectum. The superior sacral artery arises from the back of the aorta just above the bifurcation of the common iliac arteries and supplies the posterior wall of the rectum.⁵ The venous drainage of the rectum is via the superior rectal (hemorrhoidal) vein into the inferior mesenteric vein to the portal system. The middle rectal (hemorrhoidal) veins drain through internal pudendal and hypogastric veins eventually to the inferior vena cava.^{34,40}

Lymphatic Drainage

The lymphatic drainage of the proximal rectum (two thirds) is via the inferior mesenteric nodes and eventually to the para-aortic region. The distal rectum can drain via this same system following the superior rectal artery or can drain laterally to the internal iliac nodes (following the middle rectal arteries).³⁴

Figure 5 Lateral view of the rectum demonstrating the surrounding fascial components. The rectum and mesorectum are encompassed within the visceral layer of the endopelvic fascia. Denonvillier fascia can be seen anteriorly, whereas the rectosacral fascia is noted posteriorly.

PHYSIOLOGY

Storage

The rectum serves as a reservoir for fecal material until it is socially acceptable to defecate. The rectosigmoid junction and the sigmoid itself may also contribute to maintaining continence.⁴⁰ In a normally functioning rectum, increased stool volume is accompanied by passive distention of the rectum that maintains a low intraluminal pressure. This continues until a maximum volume is reached and defecation is initiated.⁴¹ The rectal wall contains mechanoreceptors that sense the filling state and level of contraction of the rectum.³⁹ Distention of the rectum sends a signal to begin the act of defecation, as described below. Rectal distention also delays both gastric emptying and intestinal transit.⁴⁰ The rectum has a low resting pressure of 5 mm Hg, with both low-amplitude and high-amplitude contractions observed on an infrequent basis. The pressure in the rectum is significantly less than that in the anal canal, and this pressure gradient helps keep the anal canal empty.⁴⁰

Anal Canal

ANATOMY

Musculature

Although there is some variation over the exact definition of the anal canal, most would agree that it exists distally

from the anal verge up to the anorectal ring proximally. The anorectal ring can be palpated at the top of the external anal sphincter/levator ani complex, whereas the anal verge can be described as the point of normal opposition of the anal opening in its usual resting state.^{34,42} The length of the anal canal may vary between 2.5 and 5 cm and is generally longer in males. The anal canal follows the length of the internal and external anal sphincters, with the external sphincter ending slightly more distal [see Figure 6]. The internal sphincter is a continuation of the circular smooth muscle layer of the rectum, whereas the external anal sphincter is composed of striated muscle circumferentially wrapping the entire anal canal.³⁹ Between the internal and external sphincter muscles exists the palpable intersphincteric groove. Historically, the external anal sphincter was described as containing three components, subcutaneous, superficial, and deep portions, whereas others consider this to be a continuous sheet of muscle closely associated with the puborectalis muscle of the levator ani.^{40,43} In addition, striated muscle fibers, called the conjoined longitudinal muscle, extend from the longitudinal muscle of the rectum to the levator ani and anorectal ring, eventually descending between the internal and external sphincter muscles to insert on the perianal skin as the corrugator cutis ani muscle.⁴⁰

The levator ani muscles essentially make up the pelvic floor. They extend bilaterally from the superior pubic rami to the ischium or coccyx and are composed of four striated muscles: the puborectalis, iliococcygeus, pubococcygeus,

Figure 6 The anal canal is visualized, noting the relation of both the internal and external sphincters. The internal sphincter is a continuation of the circular smooth muscle layer of the rectum, whereas the external anal sphincter is composed of striated muscle wrapping the anal canal. Additionally, the dentate line is shown as the junction of the anal transition zone and the squamous epithelium. At this level, the columns of Morgagni are seen extending proximally. Finally, the valves of Houston can be seen within the rectum.

and, variably, ischiococcygeus. The puborectalis is the most medially located of these muscles and is felt to serve as both a portion of the pelvic floor and the sphincter mechanism.³⁴ This muscle is U shaped, acting as a sling to pull the anorectal junction anteriorly. This results in maintenance of an acute anorectal angle, approximately 90 to 110° in normal subjects, which aids in continence.^{44,45}

Canal Lining

The lining of the anal canal is variable. The most proximal portion is composed of columnar epithelium, whereas the distal portion is made up of squamous epithelium of the anoderm (lacking hair and glands). Within the midportion of the canal, there is a transition (cloacogenic) zone where the lining may be composed of columnar, transitional, or stratified squamous epithelium.³⁹ The dentate or pectinate line is formed by the junction of this transition zone and the squamous epithelium. Beginning at this level, several longitudinal folds extend proximally and are referred to as the columns of Morgagni [see Figure 6]. The anal valves form at their base and create small pockets or crypts. These crypts are connected by ducts to a variable number of anal glands (four to 12). Most of these glands are located posteriorly and extend into the intersphincteric space, usually entering through the internal sphincter.^{34,40} More distally beyond the anal verge, the skin becomes thicker, containing glands and hair follicles usually referred to as the anal margin.³⁴

Innervation

The anal canal is supplied by both sympathetic and parasympathetic nerves, including L5 and S2-S4 (pudendal nerve). The pudendal nerve passes through the Alcock canal to exit the pelvis. It then gives rise to both the inferior rectal (S2, S3) and perineal branches (S4). The motor innervation

to the pelvic floor musculature is via S2-S4 superiorly and S4 (perineal) inferiorly, with the puborectalis muscle innervated by the inferior rectal branches. The external anal sphincter is innervated by S2-S4 (both inferior rectal and perineal branches), whereas the internal anal sphincter maintains the same innervation as the rectal circular muscle (L5 and S2-S4). The sensory innervation comes from the inferior rectal nerve, variably extending just proximal to the dentate line. Above this level, the distal rectum senses only distention via parasympathetic afferent fibers.^{34,39}

Blood Supply

The arterial supply to the anal canal may arise from both the superior (originating as the inferior mesenteric artery) and inferior (from the internal pudendal artery) rectal vessels. In addition, middle rectal arteries from the internal iliac vessels can contribute, although this is more variable. Bilaterally, the inferior rectal vessels also supply the sphincter muscles while contributing to the rich intramural collateralization of the anorectum.³⁹

The venous drainage of the anal canal is bilateral via the middle and inferior rectal (hemorrhoidal) veins into the internal iliac veins and eventually to the inferior vena cava. In addition, the external and internal rectal plexuses below and above the dentate line, respectively, communicate in the perianal and submucosal spaces,³⁴ thus contributing to the makeup of the anal cushions.⁴⁶

Lymphatic Drainage

Lymphatic drainage of the anal canal varies in relation to the dentate line. Above this line, drainage feeds to the inferior mesenteric and internal iliac nodes, whereas below it drains into inferior rectal (hemorrhoidal) lymphatics to the superficial inguinal nodes.⁴⁰

PHYSIOLOGY

Although the exact function of the anal cryptoglandular components is unknown,³⁴ their presence sets the basis for potential perianal infection. With this in mind, several potential perianal/perirectal spaces exist containing areolar and adipose tissue that can become clinically relevant. These include the intersphincteric space, the ischioanal space (lateral to the external anal sphincter and extending to the levator ani), the posterior superficial and deep postanal spaces (communicating to the ischioanal space bilaterally and separated by the anococcygeal ligament, also extending to the levator ani), and the supralelevator space.³⁹

Anal Continence

Continence relies on the successful interaction of several factors. These include stool consistency, reservoir compliance and capacity, resting and squeeze sphincter pressures, and anorectal sensation.⁴¹ The anal orifice remains closed at rest due to the continuous circumferential contraction of the sphincter mechanism. The internal anal sphincter maintains 50 to 85% of the resting tone and thus acts to avoid involuntary stool loss. The normal mean resting pressure generally ranges from 50 to 70 mm Hg. The external anal sphincter accounts for 25 to 30% of the resting tone, whereas the anal cushions contribute 15%.⁴⁰ The external anal sphincter is unique in that it remains tonically contracted despite its striated nature. It can be voluntarily contracted for 40 to 60 second periods and can generally increase tone by two to three times above the resting pressure.³⁹ In addition, the puborectalis muscle also contributes to the preservation of gross fecal continence by maintaining an appropriate anorectal angle.⁴⁰

Normal Defecation

At rest, the above factors maintain fecal continence. However, once the rectal reservoir is distended, further events are set in motion for initiating defecation. The first begins after an initiation of the left colon to propel stool contents into the rectum by normal daily peristaltic waves. Once the rectum is distended, a reflex relaxation of the internal anal sphincter occurs (rectoanoinhibitory reflex [RAIR]). This allows contact of the contents with the sensitive anal canal, allowing distinction between flatus and stool (sampling mechanism). During this time, the external anal sphincter contracts to maintain continence. If appropriate emptying is then determined, a sitting or squatting position allows straightening of the anorectal angle. By further increasing intra-abdominal pressure (straining), the pelvic floor descends and the external anal sphincter further relaxes as its pressure resistance is overcome. This results in passage of the fecal contents through the relaxed pelvic floor. After passage, a closing reflex restores normal tone and closes the anal canal.^{39,40}

Financial Disclosures: None Reported

NORMAL LABORATORY VALUES

Clinical Chemistry

<i>Analyte</i>	<i>Specimen</i>	<i>Units Used at MGH*</i>	<i>SI Units</i>
Acetoacetate	P	< 1 mg/dl	< 100 µmol/L
Albumin	S	3.5–5.5 g/dl	35–55 g/L
Aldolase	S	0–6 U/L	0–100 nkat/L
Alpha ₁ -antitrypsin	S	85–213 mg/dl	0.8–2.1 g/L
Alpha-fetoprotein	S	< 15 ng/ml	< 15 µg/L
Aminotransferases	S		
Aspartate (AST, SGOT)		0–35 U/L	0–0.58 µkat/L
Alanine (ALT, SGPT)		0–35 U/L	0–0.58 µkat/L
Ammonia, as NH ₃	P	10–80 µg/dl	6–47 µmol/L
Amylase	S	60–180 U/L	0.8–3.2 µkat/L
Angiotensin-converting enzyme (ACE)	S	< 40 U/L	< 670 nkat/L
Anion gap	S	7–16 mmol/L	7–16 mmol/L
Apolipoprotein	S		
Apolipoprotein A1		119–240 mg/dl	1.2–2.4 g/L
Apolipoprotein B		52–163 mg/dl	0.52–1.63 g/L
Apolipoprotein B-to-apolipoprotein A1 ratio		0.35–0.98	0.35–0.98
Arterial blood gases, sea level	WB, arterial		
Bicarbonate (HCO ₃ ⁻)		21–30 mEq/L	21–28 mmol/L
Partial pressure of carbon dioxide (PCO ₂)		35–45 mm Hg	4.7–5.9 kPa
pH		7.38–7.44	7.38–7.44
Partial pressure of oxygen (PO ₂)		80–100 mm Hg	11–13 kPa
β-Hydroxybutyrate	P	< 3 mg/dl	< 300 µmol/L
β ₂ -Microglobulin	S	1.2–2.8 mg/L	1.2–2.8 mg/L
	U	≤ 200 µg/L	≤ 200 µg/L
Bilirubin	S		
Total		0.3–1.0 mg/dl	5.1–17.0 µmol/L
Direct		0.1–0.3 mg/dl	1.7–5.1 µmol/L
Indirect		0.2–0.7 mg/dl	3.4–12.0 µmol/L
Brain natriuretic peptide (BNP)	P	< 167 pg/ml (age- and sex-dependent)	< 167 ng/L (age- and sex-dependent)
Calcium	S	9.0–10.5 mg/dl	2.2–2.6 mmol/L
Calcium, ionized	WB	4.5–5.6 mg/dl	1.1–1.4 mmol/L
CA15–3	S	0–30 U/ml	0–30 kU/L
CA19–9	S	0–37 U/ml	0–37 kU/L
CA27–29	S	0–32 U/ml	0–32 kU/L
CA125	S	0–35 U/ml	0–35 kU/L
Calcitonin	S		
Male		3–26 pg/ml	3–26 ng/L
Female		2–17 pg/ml	2–17 ng/L
Carbon dioxide			
Content, sea level	P	21–30 mEq/L	21–30 mmol/L
Partial pressure (PCO ₂), sea level	WB, arterial	35–45 mm Hg	4.7–5.9 kPa
Carbon monoxide content	WB		Symptoms with 20% saturation of hemoglobin
Carcinoembryonic antigen (CEA)	S	0–3.4 ng/ml	0–3.4 µg/L
Ceruloplasmin	S	27–37 mg/dl	270–370 mg/L
Cholinesterase	S	5–12 U/ml	5–12 kU/L
Chloride	S	98–106 mEq/L	98–106 mmol/L

Note: This table contains reference values for adults for laboratory tests commonly ordered at the Massachusetts General Hospital (MGH) and recorded in the Case Records. The table revises the most recently published data (Normal Reference Laboratory Values. N Engl J Med 339:1063-72, 1998). Laboratory values are expressed in the units used at the MGH and the units of the Système International d'Unités (SI units). The table is not intended to provide a comprehensive review of reference values, since this information is widely available in standard textbooks. To avoid suggesting an endorsement of commercial products by the hospital or the *Journal*, information on specific methods and instruments is not provided. Reference values are affected by many variables, including the patient population and the laboratory methods used. The ranges used at the MGH, as well as in chapters of *ACP Medicine*, may therefore not be appropriate for other institutions and may not be optimal in some situations.

Hematology and Coagulation (continued)

Analyte	Specimen	Units Used at MGH*	SI Units
Haptoglobin	S	16–199 mg/dl	0.16–1.99 g/L
Hematocrit	WB		
Male		41.0%–53.0%	0.41–0.53
Female		36.0%–46.0%	0.36–0.46
Hemoglobin			
Plasma	P	1–5 mg/dl	0.01–0.05 g/L
Whole blood			
Male	WB	13.5–17.5 g/dl	8.4–10.9 mmol/L
Female	WB	12.0–16.0 g/dl	7.4–9.9 mmol/L
Hemoglobin electrophoresis	WB		
Hemoglobin A		95%–98%	0.95–0.98
Hemoglobin A ₂		1.5%–3.5%	0.015–0.035
Hemoglobin F		0%–2.0%	0–0.02
Hemoglobins other than A, A ₂ , or F		Absent	Absent
Heparin-induced thrombocytopenia antibody	P	Negative	Negative
Homocysteine	P	0–12 µmol/L	0–12 µmol/L
Iron	S	30–160 µg/dl	5.4–28.7 µmol/L
Iron-binding capacity	S	228–428 µg/dl	40.8–76.7 µmol/L
Leukocyte count	WB	4.5–11.0 × 10 ³ /mm ³	4.5–11 × 10 ⁹ /L
Mean corpuscular hemoglobin (MCH)	WB	26.0–34.0 pg/cell	26.0–34.0 pg/cell
Mean corpuscular hemoglobin concentration (MCHC)	WB	31.0–37.0 g/dl	310–370 g/L
Mean corpuscular volume (MCV)	WB	80–100 µm ³	80–100 fl
Methemoglobin	WB	≤ 1% of total hemoglobin	
Osmotic fragility of erythrocytes	WB	No increased hemolysis as compared with normal control	Not applicable
Partial thromboplastin time, activated	P	22.1–35.1 sec	22.1–35.1 sec
Plasminogen	P		
Antigenic		8.4–14.0 mg/dl	84–140 mg/L
Functional		80%–130%	0.80–1.30
Plasminogen activator inhibitor–1	P	4–43 ng/ml	4–43 µg/L
Platelet aggregation	PRP	> 65% aggregation in response to adenosine diphosphate, epinephrine, collagen, ristocetin, and arachidonic acid	Not applicable
Platelet count	WB	150–350 × 10 ³ /mm ³	150–350 × 10 ⁹ /L
Prekallikrein assay	P	60%–140%	0.60–1.40
Prekallikrein screen	P	Deficiency not detected	Not applicable
Protein C	P		
Total antigen		70%–140%	0.70–1.40
Functional		70%–140%	0.70–1.40
Protein S	P		
Total antigen		70%–140%	0.70–1.40
Functional		70%–140%	0.70–1.40
Free antigen		70%–140%	0.70–1.40
Prothrombin gene mutation G20210A	WB	Not present	Not applicable
Prothrombin time	P	11.1–13.1 sec	11.1–13.1 sec
Protoporphyrin, free erythrocyte	WB	16–36 µg/dl RBCs	0.28–0.64 µmol/L RBCs
RBC distribution width	WB	11.5%–14.5%	0.115–0.145
Reptilase time	P	16–24 sec	16–24 sec
Reticulocyte count	WB	0.5%–2.5% RBCs	0.005–0.025 RBCs
Reticulocyte hemoglobin content	WB	> 26 pg/cell	> 26 pg/cell
Ristocetin cofactor (functional von Willebrand factor [vWF])	P		
Blood group O		75% mean of normal	0.75 mean of normal
Blood group A		105% mean of normal	1.05 mean of normal
Blood group B		115% mean of normal	1.15 mean of normal
Blood group AB		125% mean of normal	1.25 mean of normal
Schilling test, orally administered vitamin B ₁₂ excreted in urine	U	7%–40%	Not applicable
Sickle cell test	WB	Negative	Negative
Sucrose hemolysis	WB	< 10%	< 0.1
Thrombin time	P	16–24 sec	16–24 sec

Hematology and Coagulation (continued)

Analyte	Specimen	Units Used at MGH*	SI Units
Transferrin receptor	S, P	9.6–29.6 nmol/L	9.6–29.6 nmol/L
Viscosity	P	1.7–2.1	1.7–2.1

White blood cells (WBCs) [<i>see</i> Leukocyte count]			

Microbiology

<i>Specimen</i>	<i>Organisms Routinely Cultured</i>	<i>Organisms Also Reported</i>	<i>Normal Flora</i>
Throat	Group A β -hemolytic streptococci, pyogenic groups C and G β -hemolytic streptococci, <i>Arcanobacterium haemolyticum</i>	If complete throat culture is requested: <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , and yeast	α -Hemolytic streptococci, nonhemolytic streptococci, diphtheroids, coagulase-negative staphylococci, saprophytic <i>Neisseria</i>
Sputum	Pneumococci, <i>H. influenzae</i> , β -hemolytic streptococci, <i>S. aureus</i> , <i>Moraxella</i> (<i>Branhamella</i>) <i>catarrhalis</i> , gram-negative bacilli	Presence or absence of normal throat flora	Little or no normal throat flora, if specimen carefully collected
Urine	Aerobic bacteria and yeast: "abundant" if $> 10^5$ colony-forming units/ml, "moderate" if 10^4 – 10^5 colony-forming units/ml	"Few" if 10^3 – 10^4 colony-forming units/ml, "rare" if 10^2 – 10^3 colony-forming units/ml (either may indicate clinically significant bacteriuria if accompanied by pyuria, clinical symptoms, or both)	No mixed bacterial species (i.e., not more than one of the following: lactobacilli, non- β -hemolytic streptococci, diphtheroids, coagulase-negative staphylococci, or <i>Gardnerella vaginalis</i>) if specimen carefully collected
Blood	Aerobic and anaerobic bacteria, yeasts		None; common contaminants: aerobic diphtheroids, anaerobic diphtheroids, coagulase-negative staphylococci
Cerebrospinal and other fluids	Aerobic and anaerobic bacteria; yeasts (including <i>Cryptococcus</i>)	Any organism isolated	None
Stool	Enteric pathogens: <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Plesiomonas</i> , and <i>Aeromonas</i> when predominant	Moderate or abundant yeast or <i>S. aureus</i> ; presence or absence of normal gram-negative enteric flora; if special cultures requested, <i>Yersinia</i> , <i>Vibrio cholerae</i> , <i>V. parahaemolyticus</i> , or hemorrhagic strains of <i>Escherichia coli</i> (O157)	Enterobacteriaceae, streptococci, <i>Pseudomonas</i> , small numbers of staphylococci and yeast (and anaerobes that are not routinely cultured)
Wounds	Aerobic and anaerobic bacteria, yeasts		
Cervical or vaginal	Gonococci, group A β -hemolytic streptococci, pyogenic groups C and G β -hemolytic streptococci, <i>S. aureus</i> (Gram stain for diagnosis of bacterial vaginosis according to Nugent score)	Yeasts and enteric gram-negative rods if present in large numbers	

Metabolic and Endocrine Tests

<i>Analyte</i>	<i>Specimen</i>	<i>Units Used at MGH*</i>	<i>SI Units</i>
Adrenocorticotropin (ACTH)	P	6.0–76.0 pg/ml	1.3–16.7 pmol/L
Aldosterone			
Supine, normal-sodium diet	S, P	2–9 ng/dl	55–250 pmol/L
Upright, normal-sodium diet	S, P	2–5 times supine value with normal-sodium diet	
Supine, low-sodium diet	S, P	2–5 times supine value with normal-sodium diet	
Random, low-sodium diet	U	2.3–21.0 µg/24 hr	6.38–58.25 nmol/24 hr
Androstenedione	S	50–250 ng/dl	1.75–8.73 nmol/L
Cortisol	S		
Fasting, 8 A.M.–noon		5–25 µg/dl	138–690 nmol/L
Noon–8 P.M.		5–15 µg/dl	138–414 nmol/L
8 P.M. –8 A.M.		0–10 µg/dl	0–276 nmol/L
Cortisol, free	U	20–70 µg/24 hr	55–193 nmol/24 hr
Dehydroepiandrosterone (DHEA)	S		
Male		180–1,250 ng/dl	6.24–41.6 nmol/L
Female		130–980 ng/dl	4.5–34.0 nmol/L
Dehydroepiandrosterone (DHEA) sulfate	S		
Male		10–619 µg/dl	100–6,190 µg/L
Female (premenopausal)		12–535 µg/dl	120–5,350 µg/L
Female (postmenopausal)		30–260 µg/dl	300–2,600 µg/L
Deoxycorticosterone (DOC)	S	2–19 ng/dl	61–576 nmol/L
11-Deoxycortisol (8 A.M.)	S	12–158 ng/dl	0.34–4.56 nmol/L
Dopamine	P	< 87 pg/ml	< 475 pmol/L
	U	65–400 µg/day	425–2,610 nmol/day
Epinephrine			
Supine (30 min)	P	< 50 pg/ml	< 273 pmol/L
Sitting	P	< 60 pg/ml	< 328 pmol/L
Standing (30 min)	P	< 900 pg/ml	< 4,914 pmol/L
	U	0–20 µg/day	0–109 nmol/day
Estradiol	S, P		
Female			
Menstruating			
Follicular phase		< 20–145 pg/ml	184–532 pmol/L
Midcycle peak		112–443 pg/ml	411–1,626 pmol/L
Luteal phase		< 20–241 pg/ml	184–885 pmol/L
Postmenopausal		< 59 pg/ml	217 pmol/L
Male		< 20 pg/ml	184 pmol/L
Estrone	S, P		
Female			
Menstruating			
Follicular phase		1.5–15.0 pg/ml	55–555 pmol/L
Luteal phase		1.5–20.0 pg/ml	55–740 pmol/L
Postmenopausal		1.5–5.5 pg/ml	55–204 pmol/L
Male		1.5–6.5 pg/ml	55–240 pmol/L
Follicle-stimulating hormone (FSH)	S, P		
Female			
Menstruating			
Follicular phase		3.0–20.0 mIU/ml	3.0–20.0 IU/L
Ovulatory phase		9.0–26.0 mIU/ml	9.0–26.0 IU/L
Luteal phase		1.0–12.0 mIU/ml	1.0–12.0 IU/L
Postmenopausal		18.0–153.0 mIU/ml	18.0–153.0 IU/L
Male		1.0–12.0 mIU/ml	1.0–12.0 IU/L
Fructosamine	S	1.61–2.68 mmol/L	1.61–2.68 mmol/L
Gastrin	S	< 100 pg/ml	< 100 ng/L
Glucagon	P	20–100 pg/ml	20–100 ng/L
Growth hormone (resting)	S	0.5–17.0 ng/ml	0.5–17.0 µg/L
Human chorionic gonadotropin (hCG)	S	< 5 mIU/ml	< 5 IU/L
(nonpregnant women)			
17-Hydroxyprogesterone	S		
Male		5–250 ng/dl	0.15 nmol/L
Female			

*Massachusetts General Hospital.

Supine (30 min)		< 110–410 pg/ml	650–2,423 pmol/L
Sitting		120–680 pg/ml	709–4,019 pmol/L
Standing (30 min)		125–700 pg/ml	739–4,137 pmol/L
Parathyroid hormone	S	10–60 pg/ml	10–60 ng/L
Pregnanetriol	U	Age- and sex-dependent	Age- and sex-dependent
Progesterone	S, P		
Menstruating female			
Follicular		< 0.2 ng/ml	< 0.6 nmol/L
Midluteal		3–20 ng/ml	9.54–63.6 nmol/L
Male		< 0.2–1.4 ng/ml	< 0.60–4.45 nmol/L
Prolactin	S		
Female		0–20 ng/ml	0–20 μg/L
Male		0–15 ng/ml	0–15 μg/L
Serotonin	WB	50–200 ng/ml	0.28–1.14 μmol/L
	Platelets	125–500 ng/10 ⁹ platelets	0.7–2.8 amol/platelet
Sex hormone-binding globulin	S		
Male		13–71 nmol/L	13–71 nmol/L
Female		18–114 nmol/L	18–114 nmol/L
Somatostatin	P	< 25 pg/ml	< 25 ng/L
Somatomedin C (insulinlike growth factor-I [IGF-I])	S		
16–24 yr		182–780 ng/ml	182–780 μg/L
25–39 yr		114–492 ng/ml	114–492 μg/L
40–54 yr		90–360 ng/ml	90–360 μg/L
> 54 yr		71–290 ng/ml	71–290 μg/L
Testosterone	S		
Total, morning			
Female		6–86 ng/dl	0.21–2.98 nmol/L
Male		270–1,070 ng/dl	9.36–37.10 nmol/L
Unbound, morning			
Female		0.2–3.1 pg/ml	6.9–107.5 pmol/L
Male		12.0–40.0 pg/ml	416–1,387 pmol/L
Thyroglobulin	S	0–60 ng/ml	0–60 μg/L
Thyroid-binding globulin	S	16–24 μg/ml	206–309 nmol/L
Thyroid-stimulating hormone	S	0.5–4.7 μU/ml	0.5–4.7 mU/L
Thyroxine	S		
Total (T ₄)		4.5–10.9 μg/dl	58–140 nmol/L
Free (fT ₄)		0.8–2.7 ng/dl	10.3–35.0 pmol/L
Triiodothyronine	S		
Total (T ₃)		60–181 ng/dl	0.92–2.78 nmol/L
Free (fT ₃)		1.4–4.4 pg/ml	0.22–6.78 pmol/L
Vanillylmandelic acid (VMA)	U	0.15–1.20 mg/24 hr	7.6–37.9 μmol/24 hr
Vasoactive intestinal polypeptide (VIP)	P	< 75 pg/ml	< 75 ng/L

Urine Analysis

<i>Analyte</i>	<i>Units Used at MGH*</i>	<i>SI Units</i>
Acidity, titratable	20–40 mEq/24 hr	20–40 mmol/24 hr
Ammonia	30–50 mEq/24 hr	30–50 mmol/24 hr
Amylase	4–400 U/L	0.07–7.67 nkat/L
Amylase-to-creatinine clearance ratio [†]	1–5	1–5
Calcium (with dietary calcium of 10 mEq/24 hr or 200 mg/24 hr)	< 300 mg/24 hr	< 7.5 mmol/24 hr
Creatine, as creatinine		
Female	< 100 mg/24 hr	< 760 µmol/24 hr
Male	< 50 mg/24 hr	< 380 µmol/24 hr
Creatinine	1.0–1.6 g/24 hr	8.8–14 mmol/24 hr
Eosinophils	< 100 eosinophils/ml	< 100 eosinophils/ml
Glucose, true (oxidase method)	50–300 mg/24 hr	0.3–1.7 mmol/24 hr
Microalbumin	0–2.0 mg/dl	0–0.02 g/L
Oxalate	2–60 mg/24 hr	228–684 µmol/24 hr
pH	5.0–9.0	5.0–9.0
Phosphate (phosphorus)	400–1,300 mg/24 hr (varies with intake)	12.9–42.0 mmol/24 hr (varies with intake)
Potassium	25–100 mEq/24 hr (varies with intake)	25–100 mmol/24 hr (varies with intake)
Protein	< 150 mg/24 hr	< 0.15 g/24 hr
Sediment		
Bacteria	Negative	Negative
Bladder cells	Negative	Negative
Broad casts	Negative	Negative
Crystals	Negative	Negative
Epithelial cell casts	Negative	Negative
Granular casts	Negative	Negative
Hyaline casts	0–5/low-power field	0–5/low-power field
RBC casts	Negative	Negative
RBCs	0–2/high-power field	0–2/high-power field
Squamous cells	Negative	Negative
Tubular cells	Negative	Negative
Waxy casts	Negative	Negative
WBCs	0–2/high-power field	0–2/high-power field
WBC casts	Negative	Negative
Sodium	100–260 mEq/24 hr (varies with intake)	100–260 mmol/24 hr (varies with intake)
Specific gravity	1.001–1.035	1.001–1.035
Urea nitrogen	6–17 g/24 hr	214–607 mmol/24 hr
Uric acid (with normal diet)	250–800 mg/24 hr	1.49–4.76 mmol/24 hr

*Massachusetts General Hospital.

[†]The amylase-to-creatinine clearance ratio is calculated as [amylase clearance ÷ creatinine clearance] × 100.
